When the input of cholic acid is plotted against output of cholic acid, a linear relationship occurs (Fig. 1). When the results are analyzed mathematically and the equation of the straight line, output = "b" times input plus "a," was solved, it was found that "b," the slope of the line or per cent of recovery was 92 per cent, and "a," the point of intercept on the ordinate, or basal cholic acid output on the diet, was 0.046 Gm. per hour. The curve that fitted this straight line was predicted by the following equation: $On = b^nI + a\left(\frac{b^n - 1}{b - 1}\right)$, where "On" is the output of cholic acid at any subsequent hourly period, and "I" is the actual initial dose of cholic acid administered at the first return of bile. The curve predicted by this equation, which has been tested and established by previous experimental results,[10, 11] is shown in Fig. 1. The predicted homeostatic level was 0.60 Gm. per hour and that actually obtained experimentally was 0.55 Gm. per hour. The predicted cholic acid synthesis per hour was 0.046; the actual synthesis found was 0.050 Gm. The predicted recovery was 92 per cent, the actual was 91 per cent. The actual curve of output (Fig. 1) approximates fairly closely the predicted curve, though it is somewhat lower at the first, which is, in general, true in other such tests when cinchophen is not given.

Comment: The results show definitely, insofar as this dog is concerned, that repeated enterohepatic circulation of cinchophen during a forty-eight-hour period causes no decrease in cholic acid output.

DISCUSSION

The effect of cinchophen feeding on the secretion of bile has been studied under various conditions: (a) when fed for three-day periods; (b) when fed over a period of fourteen consecutive days, and thirty-three days in one animal; and (c) when making 24 enterohepatic circulations a day for two days. In no case were we able to show that cinchophen acted like a hepatotoxin as determined by bile analyses. The cholic acid output, which we believe is the most sensitive indicator of liver dysfunction, was not altered significantly. This was especially true of the average results on a number of biliary fistula dogs, although individual tests may show a greater variability in cholate synthesis. In all cases due to choleresis the cholic acid concentration in the bile was decreased, but the total cholate output remained on the average the same as the control. Similar results were obtained using potent oxidized bile acid choleretics.[7] It was also shown that cinchophen does not affect the regulation of cholic acid output by the liver. When the bile, containing cinchophen, was returned every hour during the day, the cholate output gradually increased and reached the homeostatic level predicted by a methematical equation.

We have no explanation for the increased cholesterol output due to cinchophen feeding; this occurs whenever a choleresis is produced by any procedure known. Since the cholic acid output was not simultaneously increased, the bile acid: cholesterol ratio would be decreased, which *may* tend to predispose to a precipitation of fatty acid and cholesterol in the gall bladder in the presence of a condition favoring the diffusion of bile salts from the organ.

These experiments establish cinchophen as a potent hydrocholeretic even as effective as dehydrocholic acid (decholin) or mixed ketocholanates (ketochol).

When 3 Gm. of these bile acids were administered per day, a +103 per cent increase, on the average, in volume output was obtained. One gram of cinchophen daily, whether administered over a short or long period of time, gave an average increase of +106 per cent. Comparing these substances on a gram-weight basis, cinchophen is three times more effective than dehydrocholic acid as a hydrocholeretic. The reason for this marked choleresis is not definitely known. In acute and chronic biliary fistula dogs the choleresis produced by cinchophen was associated with the excretion of 60 to 75 per cent of the administered drug. When 10 to 50 mg. of cinchophen were injected intravenously into acute and chronic biliary fistula rabbits, no hydrocholeresis occurred, and only very small amounts of cinchophen were excreted in the bile.[4] These results indicate that in the dog, but not in the rabbit, the liver is especially concerned in the excretion of cinchophen and in the process of its excretion water is excreted with the drug. It is quite probable that the ease of solubility of cinchophen in bile and its osmotic activity therein are important factors contributing to the hydrocholeresis produced by cinchophen administration in the dog.

SUMMARY AND CONCLUSIONS

One gram of "pure" cinchophen (Calco Company) was fed daily (0.5 Gm. with each meal) to 5 chronic biliary fistula dogs for three- and fourteen-day periods, and in one instance for thirty-three days, and the effect on bile volume, cholic acid, total pigment, and cholesterol outputs was determined. The amount of cinchophen recovered in the bile was also determined. It was found that this daily dose of cinchophen caused a marked hydrocholeresis associated with no significant change in cholic acid and total pigment outputs, a marked increase in cholesterol output, and a recovery of 60 to 75 per cent of the administered cinchophen.

On a gram-weight basis cinchophen is three times as effective as a hydrocholeretic as the most potent bile acid choleretic, namely, dehydrocholic acid.

When bile, formed under the stimulus of cinchophen feeding, is returned every hour during the day for two days to simulate conditions in the intact animal and to cause repeated enterohepatic circulation of the cinchophen and bile salts, the cholic acid regulatory mechanism was not disturbed and the cholate output increased and closely approximated the predicted homeostatic level of the nonmedicated animal.

In the presence of an already injured liver, cinchophen feeding did not definitely increase the severity of the hepatitis; it cannot be said that the cinchophen aided recovery, though recovery occurred during cinchophen medication.

Therefore, from our studies on chronic biliary fistula dogs, cinchophen, when fed in 1 Gm. daily doses, does not seem to act as a hepatotoxin on the basis of the criteria used. To what extent the "margin of safety" in the liver was affected by the cinchophen is not clearly determined by the type of experiment used in these studies.

DRUG PROPHYLAXIS AGAINST LETHAL EFFECTS OF SEVERE ANOXIA

IV. A Standardized Technique

Influence of Body Weight, Injection of Saline, Muscular Restraint, Rate of Ascent, and Pretreatment With Oxygen or Helium-Oxygen in Anoxic Mice

G. A. Emerson, Ph.D., and E. J. Van Liere, Ph.D., M.D.
Morgantown, W. Va.

THE influence of several medicinal agents upon resistance to acute anoxia has been studied by numerous investigators, and their reports are summarized in the first paper of this series.[1] Major variations of technique and the lack of critical examination of the findings of different workers may be responsible for discordant conclusions regarding individual agents. It is difficult to make any adequate correlation of prophylactic effects of different agents when results obtained under widely different experimental conditions are compared. Relative efficacy of different agents may be estimated accurately only through the use of one or more standard techniques, and a concept of the relative involvement of the various physiologic processes known to be concerned in the lethal action of anoxia may then be gained.

Factors of simplicity, inexpensiveness, and uniform reproducibility are of primary importance in a test of prophylactic effects against anoxia, and these considerations governed the development of the present method. Since a standard technique should involve a test of effects of agents in intact mammals, with simultaneous observation of lethal effects of anoxia in sufficient numbers of treated and untreated animals to permit statistical evaluation of results, mice are best suited for use in the proposed method.

The most easily controlled type of anoxia is anoxic anoxia, as produced by exposure to low atmospheric pressures. In contrast, controlled degrees of anemic, histotoxic, or stagnant anoxia are extremely difficult, if not impossible, to obtain,

Received for publication, August 3, 1942.

especially in large groups of animals. Further, anoxic anoxia is probably more commonly encountered in diseases of man than are the other types. It may be emphasized, however, that results of tests upon small mammals and upon lethal effects of acute exposure to simulated high altitudes necessarily have no immediate applicability to the treatment of the moderate degrees of anoxia occurring in many diseases of man or in modern aviation practice. The function of a simple test of the antagonistic action of different agents toward lethal effects of anoxia in animals is one of orientation, after which more intensive study may suggest the possible clinical usefulness of those agents which show promise in examination by more elaborate techniques. In some instances, agents which are not prophylactic against, or are even synergistic with the lethal effects of exposure to simulated high altitudes may, nevertheless, be useful in the treatment of effects of moderate degrees of anoxia. Recognition of the limitations of such agents in the treatment of severe anoxia is still necessary for full knowledge of their action.

The scope of the problem concerning various agents other than oxygen, which may have protective value in severe anoxia, has been presented elsewhere.[1] The prophylactic effects of certain convulsants,[1] narcotics,[2] and of the optical isomers of benzedrine[3] have been studied by the technique described below.

METHOD

The method involves the use of sufficiently large numbers of mice for statistical significance, simultaneous exposure of an untreated control group of equal size to the same conditions of anoxia, and a comparison by statistical criteria[4] of mortality in control and treated groups at the time approximately 50 per cent of the control mice have died from anoxia.

Young healthy adult mice of the same strain are weighed to the nearest gram and are treated intraperitoneally with the test agent dissolved in saline. Control mice are treated with an equal volume of saline at the same time. This step is unnecessary under ordinary conditions but is desirable since it makes the degree of hydration more uniform in all mice. The interval between treatment and exosure to anoxia may vary with different agents according to their time of maximum action, but, in general, should be at least one hour for the longer-acting agents to minimize effects of the difference in time of treatment of the first and last mice injected.

Exposure to anoxia is produced in a cylindrical decompression chamber resembling that of Kolls and Loevenhart.[5] This tank is constructed of ¼ inch boiler plate, oxyacetylene-welded at all seams. Its horizontal diameter is 90 cm. and its height 45 cm. The capacity is approximately 285 liter. The tank is provided with three double-strength plate glass windows, reinforced with metal bars, to permit illumination and observation; a U-shaped mercury manometer with one arm open to the outside atmosphere; two adjustable inlet valves set oppositely at the top; and an outlet connected with a vacuum pump of high capacity. Ventilation is adequate in all parts of the tank at the lowest pressures used with biologic material, and there is no possibility of accumulation of carbon dioxide under the conditions of the proposed test.

Although it is recognized that no valid single degree or even moderately narrow range of anoxia can be taken as the point at which 50 per cent of control mice die,[1] the conditions of producing anoxia should be kept rigorously constant. The varying resistance of different control groups to anoxia then probably reflects constitutional differences, for there is no correlation with the pre-experimental barometric pressure, humidity, or apparent physiologic condition of the mice. This variation in tolerance on different days necessitates the simultaneous exposure of treated and control groups to identical conditions.

Mice within the tank are rapidly exposed to a reduced pressure of about 523 mm. Hg, which simulates an altitude of approximately 10,000 feet. This pressure is maintained for ten minutes. After this period of equilibration of blood and tissue gases with this level of reduced pressure, the pressure is further reduced at a rate corresponding to an ascent of 1,000 feet per minute. Mice usually tolerate this progressive anoxia until a reduced pressure of less than 226 mm. Hg is attained within some thirty minutes after beginning exposure; this pressure corresponds to that at an altitude of 30,000 feet. Approximately 50 per cent of control mice die at the time atmospheric pressures of 170 to 141 mm. Hg are attained, which correspond to simulated altitudes of 36,000 to 40,000 feet.

Termination of exposure is governed by mortality of 50 per cent of the control mice rather than by attainment of a fixed level of anoxia. Mortality of 50 per cent of the control group affords the most significant point for statistical comparison of mortality in treated groups and estimation of either protective or harmful effects of the different agents. An ideal prophylactic would completely prevent lethal effects of anoxia at a level causing 100 per cent mortality of control mice. Except oxygen, no agent has yet been found capable of this.

After exposure, mice are observed for an additional forty-eight hours to include any possible late effects of treatment. Latent lethal effects have not been encountered with the agents tested thus far. Necropsies are occasionally made of mice dying during exposure to anoxia. Groups of mice showing pneumonitis should not be used.

The influence of diet, and especially of various hypervitaminoses, is to be studied in detail. As the test has been used to date, mice have been supplied with a standard diet and water, available at all times. The mice have been subjected to anoxia in the early afternoon. Since mice are chiefly nocturnal feeders, the stomach and small intestine are usually fairly empty at this time and the mice are in a postabsorptive state.

BODY WEIGHT

Immature animals are less susceptible to lethal effects of anoxia than are adults,[6, 7] and smaller species of animals are less susceptible to aeroembolism than are larger species.[8] In a test of tolerance to anoxia the validity of results obtained with unselected groups of young adult mice may be questioned. If the smaller mice of such groups are significantly less susceptible to anoxia, and if the numbers of smaller mice in control and treated groups do not coincide, errors might arise from this cause. Data have accumulated from previous studies which bear upon this problem.

The mean body weight of 160 mice dying during exposure for thirty minutes to severe anoxia was 16.8 ± 0.21 Gm., while the mean body weight of 240 mice surviving the same conditions of anoxia was 16.1 ± 0.17 Gm. The difference between these means is 0.7 ± 0.27, signifying[7] a p of <0.01. However, this difference is more apparent than real, for the data were integrated from results with several groups of mice of different mean body weights and of differing tolerance to anoxia, as noted by differences in mortality ratios in the individual experiments. The statistical treatment of such data cannot be considered conclusive. With smaller groups[2] simultaneously exposed and, therefore better controlled, the differences between mean body weights of mice surviving and those dying under identical conditions of anoxia were not significant, although the mice dying during anoxia were uniformly slightly heavier than those simultaneously surviving.

Of 100 mice from the same colony, 52 survived and 48 died when subjected simultaneously to severe anoxia produced according to the proposed technique. Mean body weights of these two groups were 15.6 ± 0.47 and 16.0 ± 0.40 Gm., respectively. The difference between these means is not significant, although again the survivors were slightly lighter than those dying in anoxia.

Neonatal tolerance of the rat[9] to anoxia is rapidly lost within eighteen days of postnatal life. It does not appear to be necessary that young adult mice should be carefully selected within a narrow weight range for use in tests of tolerance to anoxia. It may be noted that even if the coefficient of correlation of body weight and tolerance to anoxia were a significantly large negative value, the source of error from this cause in the proposed technique would still be dependent upon inequalities in numbers of small mice in control and treated groups. The use of large groups of mice minimizes this hazard.

INJECTION OF SALINE

It was previously reported[1] that intraperitoneal injection of 50 c.c. per kilogram of physiologic saline fifteen minutes before exposure to anoxia has no harmful effect on tolerance of mice. Thirteen of 20 mice so treated died under anoxic conditions simultaneously causing death of 14 of 20 untreated mice. Since then mice used as controls have been treated routinely with saline injections in amounts as great as 60 c.c. per kilogram giving one hour before exposure, without apparent effect on tolerance. If appreciable hydremia is produced by these massive doses of saline, the resultant anemia from dilution of the blood is insufficient to affect tolerance to anoxia. If blood volume is actually increased by these saline injections, an undesirable accentuation of the cardiac dilatation known to occur in anoxia[10] would probably outweigh any possible beneficial effects. Whatever the circulatory effects of massive doses of saline may be, however, they do not appreciably affect the lethal action of severe anoxia under the conditions of the proposed test.

MUSCULAR RESTRAINT

Mice become hyperactive during induction of anoxia, more or less in proportion to the rate of production of anoxia. In susceptible mice, and in the majority after administration of subconvulsive doses of central nervous system stimulants,[1]

this hyperactivity leads to severe clonic or epileptiform convulsions. Mice exhibiting these convulsions usually become comatose and die within a short period. Typical tetanic convulsions are infrequent in anoxic mice, and the cause of the usual convulsion in anoxia is probably cortical and sympathetic stimulation, or depression of the motor inhibitory mechanisms, rather than nervous effects of the alkalosis due to hyperpnea in early anoxia. The possibility that the hyperactivity is a response to painful stimuli from aeroemboli in joints or other tissues is negated by findings which indicate that aeroembolism is not an appreciable factor under the experimental conditions. Distention of hollow viscera due to expansion of contained gas under reduced pressure could, however, give rise to strong pain stimuli, and neuralgic pain arising from local effects on nerve trunks may occur in mice as in man.[8]

The metabolic rate is much higher during active exercise than in quiescence, and tolerance to anoxia should thereby be decreased. A significant increase in tolerance to anoxia is shown by mice fully narcotized with certain depressants[2] over that of control mice with normal activity. In order to test whether simple physical restaint would produce like results, the following two experiments were made.

Ten mice were confined, each within a 60 c.c. beaker covered with a single layer of cotton gauze. Under anoxic conditions in which 18 of 40 normal mice died when simultaneously exposed and allowed to run about inside the decompression chamber, all the 10 mice confined in the beakers died. It was felt that perhaps adequate ventilation was prevented and also that the confinement was not sufficient to restrain the mice from struggling, although none showed frank convulsions.

Twenty mice were therefore confined, each within a tube of light 14-mesh wire gauze. The tubes were made of a single thickness of the wire gauze, closed by pinching the ends and loosely stitching the longitudinal seam with light copper wire. Each tube was constructed to fit the occupant snugly but to prevent major movements of the body and full extension of the limbs. The mice were free to move easily forward along the tube but could not turn around. The usual response to confinement was sleep. Special care was taken not to make the tube too small for full respiratory movements, and the longitudinal closure was loose enough to permit a considerable amount of enlargement of the lumen with little resistance, to correct for any moderate increase in body volume at reduced pressures.

Of the 20 mice thus restrained, all died under conditions of anoxia in which only 9 of 20 control mice died when allowed the freedom of the decompression chamber.

In both experiments the rate of production of anoxia conformed to that noted in the proposed method, with a plateau for ten minutes at a simulated altitude of 10,000 feet, followed by a simulated rate of ascent of 1,000 feet per minute to 41,000 feet. With this relatively slow rate of ascent, mice show a minimal amount of excitement, although convulsions commonly precede death at the higher levels of anoxia. It may be concluded that, in testing prophylactic drugs by the proposed technique, close confinement of the experimental animals is neither beneficial nor desirable and does not resolve irregularities in oxygen

consumption due to differing activities of the mice as efficiently as does the use of a rate of production of anoxia which minimizes excitement. The harmful effects of restraint may be due to marked isometric muscular activity resulting in an increase in oxygen consumption actually greater than that in mice allowed to run about at will, and perhaps also to increased excitement and sympathicoadrenal stimulation consequent to confinement.

RATE OF ASCENT

Tolerance to anoxia is related to the rate of production of anoxia in two major ways: through development of compensatory mechanisms of the organism and through cumulative effects of prolonged anoxia. When animals are very rapidly exposed to low atmospheric pressures, limitations of the rate at which the body can lose oxygen and the possibility of occurrence of aeroembolism are also involved. Heim and Armstrong[11] have reported an increase of about 50 per cent in altitude tolerance as the rate of ascent is increased from 100 to 30,000 feet per minute. They believe that effects of anoxia upon the central nervous system are greatest with rapid production of anoxia, and that cardiovascular effects are greatest with slow ascents. It would follow that different types of drugs might exhibit different degrees of prophylaxis according to the rate of production of anoxia. Tests of lethal effects by different techniques of producing anoxic anoxia are of interest as an index of the possibility of aeroembolism. Dilution techniques[12] completely avoid any possibility of aeroemoblism but present certain technical difficulties. Anoxia was, therefore, produced in the decompression chamber at five different simulated rates of ascent and lethal effects of these different treatments were observed.

Five groups of 20 mice each were subjected to anoxia produced at one of the rates noted in Fig. 1. Curve A represents a simulated rate of ascent of approximately 15,000 feet per minute until an approximate altitude of 37,000 feet was attained, followed by a slow ascent of about 100 feet per minute for ten minutes. Approximately one-half of the mice died at a simulated altitude of 37,500 feet, six minutes after beginning exposure to anoxia. Curve B represents a simulated rate of ascent of about 1,000 feet per minute. One-half of the mice died at a pressure corresponding to 42,000 feet, thirty-eight minutes after beginning exposure to anoxia. Curves C and D represent rates of ascent coinciding with that of curve A until approximate altitudes of 11,000 and 21,500 feet, respectively, were attained. These levels of anoxia were then maintained for ten minutes, after which a further simulated rate of ascent of approximately 2,000 feet per minute was begun. One-half of the mice so treated died at a simulated altitude of 37,000 feet twenty-three minutes after beginning exposure, and at a simulated altitude of 42,000 feet twenty minutes after beginning exposure, for treatments represented by curves C and D, respectively. Curve E represents rapid ascent to about 32,000 feet, maintenance of this level for ten minutes, and a further ascent at the rate of about 1,000 feet per minute. One-half of the mice treated in this way died at an approximate altitude of 32,000 feet, nine minutes after beginning exposure to anoxia.

Curves A, D, and E terminate at the level at which the last animal of the group died. Two of the 20 mice subjected to the treatment represented by

curve C recovered after exposure, despite brief apnea in both. Seven of the 20 mice subjected to the slow rate of ascent represented by curve B recovered after exposure. Comparison of the minimal pressures attained in the different treatments is meaningless, since these pressures reflect the tolerance of only the most resistant mice in each group. A more significant comparison is obtained by consideration of the levels of anoxia at which 50 per cent of the mice died.

The above tests were made consecutively, under identical conditions of barometric pressure, humidity, and temperature, and all mice were of the same strain with identical pre-experimental care and diet. The results indicate that aeroembolism is not a significant factor as a cause of death under the conditions of the proposed test. After a return of mice to room conditions, even those subjected to the most severe conditions noted in Fig. 1 showed no gaseous emboli in vessels of the pia mater or in the abdomen.

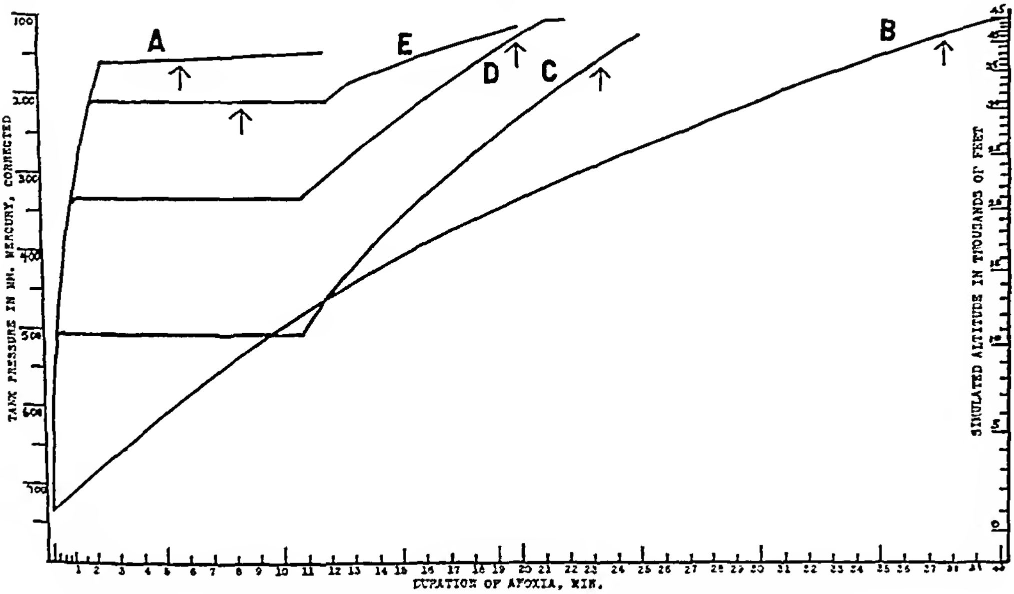

Fig. 1.—Effect of simulated rate of ascent on tolerance of mice toward lethal effects of anoxia ↑ denotes point at which one-half of the mice died.

The results also indicate that a simulated rate of ascent of 1,000 feet per minute is slow enough to permit various compensatory changes in mice but is rapid enough to avoid any marked cumulative effects of anoxia.

PRETREATMENT WITH OXYGEN

Thirty mice were placed in an 8 liter sealed glass chamber containing 1 kg. of soda lime so placed that the mice did not have access to it. Oxygen was passed through the chamber at a rate of 2 liters per minute for ninety minutes. The mice were then placed in the decompression chamber together with 30 mice which had been kept under normal atmospheric conditions. The pressure was quickly reduced to a simulated altitude of 20,000 feet and was held at this level for ten minutes. The pressure was then further reduced at a rate simulating an ascent of 2,000 feet per minute until an altitude of about 38,000 feet was attained, and this degree of anoxia was then maintained. The total time of exposure was thirty minutes.

Twenty-one of the 30 previously untreated mice died from anoxia, while only 14 of the 30 mice which received oxygen prior to exposure died. Although this difference in mortality is large, it cannot be considered as a statistically significant difference since its p is greater than 0.05.

The rate at which oxygen was supplied during the pretreatment period is equivalent to a complete change of the atmosphere within the chamber every 3 to 3.5 minutes, or a total of 26 to 30 complete changes in ninety minutes. Under these conditions appreciable denitrogenation of the tissues occurs. The significance of this in regard to aeroembolism is discussed below. Consideration of the factors involved in this experiment led to observation of effects of pretreatment with helium-oxygen.

PRETREATMENT WITH HELIUM-OXYGEN

Thirty mice were treated in the same way as in the pretreatment with oxygen alone, except that pure oxygen was passed through the chamber at the rate of 2 liters per minute for only thirty minutes. The chamber was then rapidly flushed with 18 liters of helium, quickly followed by 30 liters of a mixture of 80 per cent helium and 20 per cent oxygen. The outlet tube from the chamber was closed and the chamber was connected with a reservoir of pure oxygen maintained at atmospheric pressure, thus permitting the flow of oxygen at the rate at which the soda lime within the chamber absorbed carbon dioxide excreted by the mice. Mice were kept in this atmosphere of 80 per cent helium and 20 per cent oxygen for one hour, during which period the chamber was flushed three times with 80 per cent helium and 20 per cent oxygen in order to remove any accumulated nitrogen.

The mice were then subjected to anoxia in the decompression chamber, together with 30 previously untreated mice. The procedure of producing anoxia was the same as with mice pretreated with oxygen alone.

Of the 30 control mice, 11 died during the exposure to anoxia while only 6 of the 30 mice pretreated with helium-oxygen died. Again this difference in mortality is large, but it is not statistically significant. The implications of these data are discussed below.

DISCUSSION

Factors which may influence results in the proposed test have been mentioned, and their significance has been appraised experimentally. Body weight of young adult mice is not correlated significantly with resistance to anoxia. Therefore, groups of young adult mice need not be carefully selected within a narrow weight range for use in the test. Massive intraperitoneal injections of saline have little effect on tolerance to anoxia, so that control groups need not receive amounts of saline equivalent to those given as a solvent for the test agents, although this treatment with placebo injections in control mice is probably desirable to render the degree of hydration more uniform in all mice. Muscular restraint, as produced by two methods, fails to increase tolerance of mice to simulated high altitudes and appears markedly detrimental, at least under conditions of decompression which minimize excitement in mice allowed the freedom of the chamber.

The remaining factors involve the important question of the possibility of occurrence of aeroembolism in mice subjected to the proposed experimental technique. If an appreciable number of deaths under the experimental conditions can be ascribed to aeroembolism rather than to anoxia, these conditions obviously cannot yield a significant measure of prophylactic actions of drugs against lethal effects of anoxia.

Effects of decreased atmospheric pressures upon the blood and spinal fluid have been studied intensively.[8, 13] Armstrong[8] has pointed out that in man an acute exposure to decreased atmospheric pressure, such as might occur in sudden failure of a sealed cabin in aircraft at high altitudes, would result in anoxia at altitudes below 30,000 feet, in aeroembolism at altitudes between 30,000 and 63,000 feet, and in rapid vaporization of body fluids at altitudes above 63,000 feet. In experimental observations, however, he[8] found that while goats may show the presence of nitrogen bubbles in blood during exposure to high altitudes, this phenomenon is not apparent in rabbits subjected to a simulated rate of ascent of 40,000 feet in forty seconds. With goats nitrogen bubbles appear in the spinal fluid at a simulated altitude of 18,000 feet, and increase as ascent is continued. Intracranial pressure simultaneously increases.

Walsh and Boothby[13] investigated effects of low atmospheric pressure on spinal fluid in man and found that exposure to simulated altitudes as low as 10,000 to 12,000 feet elicits the appearance of fine bubbles "like those arising from champagne" and that these increase in size and number until an altitude of 28,000 feet is attained. On maintenance of this level for five minutes, the bubbles disappear. Intraspinal pressure increases progressively by some 3 cm. after the appearance of bubbles. Similar findings were observed in another subject partially denitrogenated by prior exposure to an atmosphere of pure oxygen. In vitro tests substantiated these results. With a monkey, however, a roentgenogram did not disclose the presence of any accumulation of gas in the ventricles of the brain even after a rapid ascent to a simulated altitude of 40,000 feet.

From these reports it may be concluded that smaller mammals withstand lower levels of atmospheric pressure before exhibiting formation of nitrogen bubbles in blood and spinal fluid. This characteristic is probably related to different rates of elimination of nitrogen due to differences in circulatory rates. Thus, in an atmosphere of pure oxygen, 95 per cent denitrogenation occurs within two hours in dogs and four hours in man, and the circulatory rate of the dog is about twice that of man, expressed in terms of blood supply per kilogram of body weight.[14] Extrapolation of results with rabbits and monkeys to mice appears justifiable, and the possibility of occurrence of aeroembolism in mice under the conditions of the proposed test would seem remote. Three points of evidence in the present study support this view and suggest that there is no hazard of aeroembolism under the experimental conditions. A further, though minor, confirmatory point involves the lack of a significantly demonstrable difference in tolerance in adult mice of different body weight: although there may be no valid relative difference in amount of fatty tissue in large and small mice, it is reasonable to assume a difference in absolute amount of body fat and fatty tissue acts as a reservoir for nitrogen, favoring aeroembolism.[6]

First, consideration of the mortality of mice subjected to different rates of production of decreased atmospheric pressure reveals that no effects definitely attributable to aeroembolism occur even with the most rapid rates of ascent. There is no sudden, large increase in lethal effects of exposure to low pressure other than the moderate influences related to failure of compensatory mechanisms antagonizing anoxia. However, to minimize further any possibility of aeroembolism, the proposed test utilizes a partial denitrogenation by exposure for ten minutes to a reduced pressure easily tolerated by the mice; i.e., a plateau at 10,000 feet. Absence of persistent aeroemboli in vessels of mice after drastic anoxic treatment, following return to normal atmospheric pressure, does not prove that aeroemboli do not occur at the height of anoxia, but all considerations indicate that aeroembolism is not an important factor even in mice subjected to rapid ascent.

Second, exposure to pure oxygen for ninety minutes before the mice are subjected to anoxia results in a significant denitrogenation of the tissues, probably of more than 95 per cent. Such treatment does not significantly reduce the lethal effects of anoxia as produced in the proposed test. Although there is no recognized reservoir for oxygen save the small effect of complete saturation of myohemoglobin,[12] minor physiologic effects of pretreatment with oxygen might be sufficient to explain the slightly increased tolerance of pretreated mice. Certainly there is not the major difference in mortality between pretreated and control mice which could be expected if aeroembolism were a major factor in the lethal effects of the conditions to which the mice are subjected in the proposed test.

Finally, pretreatment with helium-oxygen also does not significantly reduce lethal effects in mice. At atmospheric pressure helium is liberated from tissues about twice as fast as nitrogen and, therefore, should have less tendency to become supersaturated in blood and tissues during exposure to low pressures.[15] If aeroembolism were an important cause of death in the majority of the control mice exposed to the simulated high altitudes, pretreatment with helium-oxygen should significantly decrease this mortality.

It is to be noted that the possibility of an infrequent instance of aeroembolism occurring under the conditions of the proposed test is not ruled out conclusively by any one of the three factors discussed. Taken together, however, there is a strong indication that aeroembolism occurs so rarely, if at all, under these conditions that it does not invalidate interpretation of results obtained through a decompression technique as a true expression of tolerance of the mice to anoxia.

SUMMARY

A standard test of effects of drugs upon tolerance to anoxia is proposed. The method involves exposure of large groups of mice to low atmospheric pressures produced by a rigorously fixed technique in a decompression chamber allowing adequate ventilation, with simultaneous exposure of an equal number of untreated mice to the same conditions, and a comparison of mortality in control and treated groups by statistical criteria at the time 50 per cent of the control mice have died from anoxia. The function of this simple test is one of preliminary orientation, to obtain a measure of relative efficacies of different agents in com-

bating lethal effects of anoxia. For reasons discussed results cannot be considered applicable to therapy in man without further investigation. The influence of certain variable factors, including those which might affect the possible occurrence of aeroembolism, is studied. The results indicate that the test measures tolerance to anoxia and is not significantly affected by other factors.

DRUG PROPHYLAXIS AGAINST LETHAL EFFECTS OF SEVERE ANOXIA

V. Agents Affecting the Autonomic Nervous System

G. A. Emerson, Ph.D., and E. J. Van Liere, Ph.D., M.D.
Morgantown, W. Va.

Effects of anoxic anoxia on the activity of the autonomic nervous system have been summarized recently by one of us.[1] The bulk of the literature indicates that moderate or severe anoxia increases activity of the thoracolumbar division and evokes a discharge of epinephrine from the adrenal glands. The influence of anoxia on the craniosacral division is not as clear, although a compensatory stimulation might be expected even in the absence of direct effects. Monge[2] described an increased activity of the oculocardiac reflex in anoxic subjects, and others whom he cites have claimed that effects of atropine are diminished at high altitudes. Ury and Gellhorn[3] noted that in rabbits the threshold for reflex mydriasis by stimulation of the sciatic nerve is increased in anoxia, which may be interpreted as an indication of increased inhibition through the oculomotor nerve. Gasser and Loevenhart[4] found the cardio-inhibitory center less susceptible to anoxia than the vasomotor center, both in the primary stimulation and subsequent depression. On the other hand, there is a controversy[1] as to whether tachycardia in anoxia is due to stimulation of the accelerator mechanism or to vagal depression. The recognized disturbance of sleep at high altitudes may perhaps indicate in part a preponderance of adrenergic over cholinergic stimulation by anoxia.

Since the work of Gomez and Pike,[5] several reports have emphasized the relative resistance of autonomic ganglia to structural damage by anoxia. Autonomic neurons are much less susceptible than the central nervous system. Thoracolumbar ganglia are more susceptible than Auerbach's plexus to loss of function in anemic anoxia. Medullary centers controlling autonomic activity are more susceptible than the ganglia, and presumably the higher "centers" are still more susceptible.

Cats deprived of the larger part of their autonomic nervous system quickly die from degrees of anoxia ordinarily sublethal.[6] Thyroidectomy, which is said[7] to reduce susceptibility to anoxia, decreases the effects of epinephrine and increases cholinergic responses[8] while hyperthyroidism has the opposite effects.

Binet and Strumza[9, 10] and a few other observers have made direct studies of effects of several sympathicomimetic amines at lethal levels of anoxia. These reports are considered in the discussion of the present results.

A comprehensive survey of prophylactic actions of representative autonomic agents has been lacking and was, therefore, undertaken as a part of a series of

studies designed to yield a preliminary evaluation of effects of different classes of drugs in anoxia for direction of more intensive pharmacologic study without which no clinical application of the results should be made. Maximal effects were desired in the present work, and conclusions as to the effects of clinical doses in man are not necessarily justified.

METHOD

A standardized technique of quantifying actions of drugs on lethal effects of anoxic anoxia was used. This method has been studied critically.[11] In brief, it depends on the comparison of mortality in groups of treated and control mice simultaneously exposed to identical conditions of anoxia produced in a manner which, we believe, avoids all such factors as aeroembolism which would invalidate the results.

Forty-one agents acting on the autonomic system or closely related to agents which do so were tested with small groups of mice. In 14 instances results were sufficiently suggestive to justify study with larger groups. The agents are divided into six classes, five of which are noted in Tables I to V. The sixth group is that of adrenergic sensitizers, of which cocaine was taken as the sole example.

TABLE I

EFFECT OF SYMPATHETIC STIMULANTS AND RELATED AGENTS ON RESISTANCE TO ANOXIA

AGENT	DOSE (MG./KG.)	MORTALITY RATIOS	
		TREATED MICE	CONTROL MICE
Phenethylamine hydrochloride	50	10/20	9/20

Table V

Effects of Agents Acting on Autonomic Ganglia on Resistance to Anoxia

Agent	Dose (mg./kg.)	Mortality Ratios	
		Treated Mice	Control Mice
Nicotine (free base)	0.5	4/10	5/10
Lobeline sulfate	2	4/10	5/10
Sparteine sulfate	25	6/19	7/20

All agents were administered intraperitoneally. Those with prolonged effect were given thirty to sixty minutes before exposure of the mice to anoxia, while agents with brief duration of action were given within ten minutes of exposure. Lethal degrees of anoxia are not attained until some forty minutes after beginning exposure with the method used, however, so that results with short-acting agents must be interpreted cautiously.

RESULTS

Tables I to V present detailed results of treatment with different classes of agents affecting the autonomic nervous system, and Table VI is a summary of these data with the addition of results with cocaine which have been reported previously.[12] The mortality ratios signify the number of mice dying from anoxia divided by the total number of mice exposed. Mortality ratios for untreated control groups simultaneously exposed to anoxia are noted to the right of the corresponding treated groups. These bear no relation to mortality ratios of other control groups, since anoxia was terminated at different levels for different pairs

TABLE VI

SUMMARY OF EFFECTS OF GROUPS OF AGENTS ON RESISTANCE TO ANOXIA

GROUP	MORTALITY RATIOS		PER CENT MORTALITY	
	TREATED	CONTROLS	TREATED	CONTROLS
Sympathicomimetic agents (Table I)	342/500	168/500	68.4	33.6
Sympathetic sensitizer (cocaine)	13/20	11/20	65.0	55.0
Sympathicolytic agents (Table II)	52/150	76/150	34.7	50.7
Ergotamine, yohimbine, and 883F (Table II)	19/70	42/70	27.1	60.0
Parasympathicomimetic and related agents	57/153	58/160	37.3	36.3
Choline esters and neurine (Table III)	18/40	17/40	45.0	42.5

Parasympathicolytics and trasentin (Table IV)	58/120	43/120	48.3	35.8
Ganglionic agents (Table V)	14/39	17/40	35.9	42.5

*Physostigmine, pilocarpine, arecoline, and prostigmine in a dose of 0.1 mg. per kilogram.

of treated and control groups and the resistance of mice to anoxia is not constant on different days.[12]

Following exposure to anoxia, the survivors were observed for twenty-four hours. No late effects of anoxia in treated mice were recognized.

Statistical treatment[13] of the combined data in Table VI demonstrates a significantly harmful effect of adrenergic and parasympathicolytic agents, and significant prophylactic effects of sympathicolytic agents and those with prolonged cholinergic effects. Short-acting cholinergic agents, those acting on autonomic ganglia, and the adrenergic sensitizer, cocaine, had no significant effects. The propriety of treating the combined data statistically may be questioned, but it is supported by the findings for individual agents. Significantly harmful effects were found for ephedrine, benzedrine, and its optical isomers, and propadrine, while significant prophylaxis was found with physostigmine, ergotamine, and the synthetic sympathicolytic, 883F. Other agents with similar actions would probably show significant effects if larger groups of mice were used.

DISCUSSION

A brief consideration of the properties of the individual agents is desirable, since none has a single, pure action on the autonomic nervous system. In several instances, lack of conformity with the general trend of the results is due to the short action of the agents in question. Otherwise, conclusions reached through consideration of results with groups of agents are generally supported for individual agents; that is, those with stronger adrenergic or parasympathicolytic activity tend to decrease resistance to anoxia more strongly, while cholinergic and sympathicolytic properties tend to prevent lethal effects of anoxia.

Adrenergic and related substances. Results with epinephrine and the isomers of benzedrine have been taken from previous reports[12, 14] in which their pertinent properties are adequately discussed. The sympathicomimetic action of epinephrine is the greatest of the agents studied, but this action is brief. Further, discharge of epinephrine from the adrenals at lethal levels of anoxia would make it unlikely that additional epinephrine or other sympathicomimetic agents would have desirable effects. Despite this improbability, ephedrine,

norephedrine, pseudonorephedrine, and benzedrine are claimed[9, 10] to delay respiratory failure in dogs subjected to fulminating anoxia. None has prophylactic value under the present experimental conditions. Synephrine, which is strongly adrenergic, is considered unsuitable[15] for the therapy of mountain sickness. These observations emphasize that agents which may be of temporary benefit in treating fulminating anoxia do not necessarily have any prophylactic value and may actually be harmful if used for prophylaxis. A study[12] of prophylactic effects of 12 respiratory stimulants confirms this. Conversely, agents such as alcohol with appreciable prophylactic activity are not necessarily suited for treatment of anoxia.[16]

Phenethylamine exerts mainly nicotine-like actions while phenethanolamine has a more purely adrenergic action.[17] Pseudoephedrine is weaker than ephedrine in most of its sympathicomimetic effects and is said to be a myocardial stimulant while ephedrine is depressant in full dose.[5] Hordenine causes vagal stimulation in small dose and paralyzes the vagus center in large dose but has definite adrenergic activity.[5] Tyramine may be considered as an adrenergic sensitizer similar to ephedrine; its effect in anoxia is not statistically significant. Norephedrine and pseudonorephedrine together constitute propadrine, of which the commercial preparation contains also a small amount of ammonium chloride. Despite the empirical use of ammonium chloride as a prophylactic against mountain sickness, propadrine is not less harmful than either of its fractions. Mescaline shares with benzedrine an enhanced activity on the central nervous system, but its effect in anoxia is not significant, although the stronger central stimulant isomer of benzedrine is significantly more harmful than the weaker isomer at one dose level.

Dihydroxyphenylalanine, "dopa," has no appreciable adrenergic properties but is related to the phenolic sympathicomimetic amines. Under the conditions of anoxia used, the redox functions of these agents are not of sufficiently long duration to act at lethal levels of anoxia. Octin, an aliphatic amine, has greater spasmolytic and less pressor effect than the true adrenergic agents, and its action in anoxia indicates that bronchodilatation is not an important factor in prophylaxis.

Sympathicolytic agents. The first three agents in Table II paralyze adrenergic functions for a relatively long period. The two dioxane derivatives act as mild narcotics in doses of 10 mg. per kilogram. Aspidospermine is a weak sympathicolytic and causes pulmonary edema and hyperemia.[8]

Cholinergic and related substances. The choline derivatives and neurine have a transient action. The remainder of the agents in Table III, except betaine, cause prolonged cholinergic effects. Physostigmine is most effective in anoxia in a dose within the lethal range, but prostigmine appears definitely harmful in high dose. Betaine is wholly inert as to cholinergic activity, but its chloride is strongly acid and is included as a control for the other salts used.

Belladonna group and trasentin. Although none of these agents has a significant harmful effect in anoxia, there is a close relationship between the parasympathicolytic potency and the detrimental effects in anoxia. Stimulant effects of these agents on respiration possibly mask the full effects of peripheral pa-

ralysis of the craniosacral nerves in anoxia. Hyoscine apparently does not act as a strong respiratory depressant in anoxia, and it is of interest that an antagonism of the respiratory effects of hyoscine and morphine has been noted clinically.[18] Properties of the five commonly used belladonna alkaloids need no further exposition. Duboisine is variously described as equivalent to hyoscyamine,[19] or to a mixture of hyoscyamine, hyoscine, and minor alkaloids.[20] Trasentin, or diphenylacetyldiethylaminoethanol hydrochloride, is not parasympathicolytic but is included as a control for the spasmolytic effects of the group. It may be noted that its effects in anoxia differ appreciably from those of octin.

Ganglionic agents. In addition to effects on autonomic ganglia, these agents have marked central effects, mediated in part through the carotid sinus mechanism. The resultant respiratory stimulation is brief. Thus, lobeline may be of some value in treatment of asphyxia neonatorum but is not prophylactic in anoxia. Sparteine affects autonomic ganglia but also potentiates epinephrine.[21] It acts as a myocardial poison and is included since it has been used clinically in conditions in which anoxia may occur; i.e., asthma and cardiac disease.

SUMMARY

Certain cholinergic and sympathicolytic agents have significant prophylactic actions against lethal effects of anoxic anoxia in mice, while adrenergic and parasympathicolytic agents tend to increase the lethal effects. Other classes of autonomic drugs are without appreciable effect. Differences in the therapeutic and prophylactic efficacies of individual agents are discussed.

COMPARATIVE TOXICITY OF PENTOBARBITAL IN THE NEWBORN AND ADULT RAT*

B. Etsten, F. A. D. Alexander, and H. E. Himwich
Albany, N. Y.

Recent studies have disclosed that newborn rats, dogs, cats, and rabbits exhibit an extraordinary tolerance to anoxia[1] produced by the inhalation of pure nitrogen, helium, or carbon dioxide, or by the volatile narcotics, nitrous oxide and cyclopropane. The adult rat usually dies within a period of three minutes when respiring either pure nitrogen or these depressant drugs, whereas the newborn of the same species survives for approximately fifty minutes in nitrogen and nitrous oxide, and twenty-five minutes in cyclopropane and carbon dioxide. The newborn rats are also relatively resistant to alcohol[2] and to the acute lethal effects of morphine.[3] On the other hand, the newborn appears relatively more sensitive than the adult to the nonvolatile depressant drug, pentobarbital. Rosenfeld and Snyder,[4] and Windle and Becker[5] have shown that the barbiturates depress the respiratory efforts of the fetus more than those of the pregnant mother. In view of the discrepancy between the tolerance of the newborn to anoxia and the volatile anesthetics and the susceptibility of the fetus to barbiturates, the present comparative studies of the susceptibility and resistance of the newborn and adult rat to pentobarbital sodium were made. These observations include fetuses and pregnant rats near term.

In an effort to determine the mechanism of the action of barbiturates, the effect of pentobarbital on the survival time of the newborn in nitrogen and nitrous oxide was examined.

METHOD

Rats 1 to 2 days old and mature animals were injected intraperitoneally with various concentrations of pentobarbital. The tolerance of the newborn was

*From the Departments of Anesthesia and Physiology and Pharmacology, Albany Medical College, Union University, Albany, N. Y.

Aided by a grant from the Albion O. Bernstein Memorial Fund.
Received for publication, August 3, 1942.

compared with that of the adult animal given an equivalent concentration of barbiturate. In this manner the lethal dose for the newborn and the adult was determined. Cessation of respiration and inability to evoke respiration were taken as the criteria of the lethal effect.

Pregnant rats were subjected to various concentrations of pentobarbital. After allowing sufficient time for the absorption of the drug, cesarean section was done in order to study the effect on the fetus. One rat already in labor was injected with an anesthetic dose of pentobarbital, and the fetuses were observed after expulsion from the uterus. Infant rats subjected either to anesthetic or lethal doses of pentobarbital were placed in an atmosphere of pure nitrogen. The survival time of these newborn rats was compared with that of the uninjected litter mate controls. Other infant rats who had received lethal doses of pentobarbital were injected with various concentrations of metrazol to determine the combined effects of both drugs on respiratory depression and survival period. A control study was made to ascertain the tolerance of the newborn for metrazol.

TABLE I

SURVIVAL PERIOD OF NEWBORN AND ADULT RATS INJECTED WITH PENTOBARBITAL (0.1%)

NO. OF ANIMALS	AGE GROUP	PENTOBARBITAL (MG./GM.)	RESULTS	AVERAGE SURVIVAL TIME
3	Newborn	0.8	3 died	30 minutes
4	Newborn	0.5	4 died	35 minutes
4	Newborn	0.4	4 died	45 minutes
20	Newborn	0.3	16 died	60 minutes
8	Newborn	0.2	8 lived	Anesthetic dose
1	Adult	0.2	1 lived	No anesthesia
3	Adult	0.3	3 lived	No anesthesia
3	Adult	0.4	3 lived	Surgical anesthesia
6	Adult	0.5	6 lived	Surgical anesthesia
1	Adult	0.6	1 died	32 minutes
1	Adult	0.7	1 died	30 minutes

RESULTS

Table I reveals that 0.3 mg. per gram of body weight of pentobarbital is the minimal fatal dose for the rat 1 to 2 days old. Sixteen of 20 newborn animals died after an average survival period of sixty minutes, with a range of thirty to ninety minutes. All of 8 newborn animals receiving 0.2 mg. per gram survived, whereas 4 animals receiving 0.4 mg. per gram all died within forty-five minutes. The minimal fatal dose for adult rats of our colony is 0.5 mg. per gram of body weight. Each of 6 adult rats receiving this dose died after an average survival of thirty minutes. Adult rats receiving 0.3 mg. per gram were not even anesthetized. Those receiving 0.4 mg. per gram exhibited a short period of surgical anesthesia. In Table II is disclosed the sensitivity of fetal rats to pentobarbital. Three pregnant rats received pentobarbital in doses ranging from 0.3 mg. per gram to 0.4 and 0.5 mg. per gram of body weight. Twenty-nine fetuses were born spontaneously or were delivered by cesarean section fourteen minutes after the injection of the drug. All fetuses died from ten to forty minutes after the delivery, and the extrauterine survival time decreased with increasing dosage of pentobarbital. In contrast all the mothers with the exception of one which received 0.5 mg. per gram survived.

TABLE II

EFFECTS OF PENTOBARBITAL (0.1%) ON FETAL RATS

NO. OF PREGNANT RATS	PENTOBARBITAL (MG./GM.)	PROCEDURE	NO. OF FETUSES	RESULTS	SURVIVAL PERIOD OF FETUSES
1	0.3	Cesarean section	9	9 died	40 minutes
1	0.4	Cesarean section	10	10 died	10 minutes
1	0.5	Section after death	10	10 died	10 minutes
1	0.3	Spontaneous delivery	4	3 died	45 minutes

TABLE III

EFFECTS OF PENTOBARBITAL (0.1% AND 0.3%) AND ANOXIA ON SURVIVAL PERIOD OF NEWBORN RATS

NO. OF NEWBORN RATS	PENTOBARBITAL (MG./GM.)	AGENT	RESULTS	AVERAGE SURVIVAL TIME
3	0.1	Nitrogen	3 died	50 minutes
3	0.1	Nitrous oxide	3 died	50 minutes
2	0.1	Nitrogen	2 lived	40 minutes
6	0.3	Nitrogen	6 died	25 minutes

A rat which had delivered 4 of her fetuses was injected with 0.3 mg. per gram of pentobarbital. Eighteen minutes after the injection one fetus was born spontaneously. It exhibited no signs of respiratory depression and survived. Three fetuses born from forty-five to ninety minutes after the injection were in apnea. Respirations could not be evoked and all 3 died. Table III presents the data on infant rats placed in an atmosphere of nitrogen or nitrous oxide after receiving 0.1 mg. per gram, an anesthetic dose, or 0.3 mg. per gram, a lethal dose, of pentobarbital. Six newborn rats receiving the lower dose survived for fifty minutes either in nitrogen or nitrous oxide. However, the infant rats with the larger dose survived on an average only twenty-five minutes.

TABLE IV

EFFECTS OF METRAZOL (10 PER CENT) ON SURVIVAL PERIOD OF NEWBORN RATS

NO. OF NEWBORN RATS	METRAZOL (MG./GM.)	EFFECT	RESULT
6	5.0	Convulsion	6 died
5	4.0	Convulsion	5 died
5	3.0	Slight convulsion	5 lived
5	2.0	Slight convulsion	5 lived

Table IV shows the results of the experiments made to determine the lethal dose of metrazol for newborn rats. Five animals injected with 3.0 mg. per gram of body weight exhibited mild convulsive movements and survived. With larger doses 4.0 and 5.0 mg. per gram the animals died as a result of the severe convulsions.

TABLE V

EFFECT OF PENTOBARBITAL (0.3 MG./GM. BODY WEIGHT) AND METRAZOL (10%) ON SURVIVAL PERIOD OF NEWBORN RATS

NO. OF NEWBORN RATS	METRAZOL (MG./GM.)	INJECTION TIME AFTER PENTOBARBITAL	RESULT
5	7.5	20 minutes	5 lived
5	5.0	15 minutes	5 lived
5	4.0	22 minutes	5 lived
5	3.0	35 minutes	5 lived

Table V presents the effects of various concentrations of metrazol on infant rats given a lethal dose of pentobarbital. It may be seen that 3.0, 4.0, and 5.0 mg. per gram of metrazol successfully antagonize lethal doses of pentobarbital.

DISCUSSION

In contrast with the extraordinary tolerance of the newborn rat to the volatile anesthetics, nitrous oxide and cyclopropane, the infant rat both ante partum and post partum is more sensitive to pentobarbital than is its mother. The newborn rat died with a dose of 0.3 mg. per gram and the adult with 0.5 mg. per gram. Pentobarbital depresses the respiratory centers so that the animal cannot be resuscitated and dies from anoxia. Since the newborn rat is more tolerant of anoxia than is the adult, the greater sensitivity of the infant rat to barbiturate cannot be explained simply by the anoxia produced as a result of the depression of respiration. The mechanism which normally facilitates the survival of the newborn rat during anoxia depends upon the anaerobic splitting of carbohydrate with the formation of lactic acid.[6, 7] It is true that nonfatal doses of barbiturate do not shorten the survival period of the newborn rats in an atmosphere of nitrogen. However, a fatal dose of pentobarbital (0.3 mg. per gram) which permits the infant rat to survive for sixty minutes in air cuts down the survival period in nitrogen to twenty-five minutes. This is half the period in which the infant rat can survive in pure nitrogen. It would, therefore, seem that pentobarbital inhibits the mechanism for the anaerobic production of energy from carbohydrate. One path of the breakdown of carbohydrate involves a series of the same intermediates from glucose to the formation of pyruvic acid irrespective of the presence or absence of oxygen. Pyruvic acid, however, is then either oxidized to carbon dioxide and water, or in the absence of oxygen is converted to lactic acid. It would, therefore, seem that pentobarbital interferes with some stage in glucose metabolism before the formation of pyruvic acid. In any case lactic acid formation is not increased by the barbiturates.[8] Quastel and Wheatley[9] have previously indicated that barbiturates depress aerobic sources of cerebral energy. The present evidence reveals that barbiturates probably also inhibit the anaerobic breakdown of carbohydrate.

Though the newborn rat is susceptible to pentobarbital, it is able to withstand a lethal dose with the aid of metrazol. The mutual antagonism between the two drugs is emphasized because the dose of metrazol used would have been lethal for an animal that had not received pentobarbital.

CONCLUSIONS

1. The newborn rat is more susceptible than the adult to pentobarbital both ante partum and post partum. The lethal dose for the newborn rat is 0.3 mg. per gram, and for the adult 0.5 mg. per gram.

2. Evidence is afforded indicating that pentobarbital inhibits the development of the anaerobic energy required for survival in the absence of oxygen.

3. Doses of pentobarbital and metrazol, which when given singly are lethal, may successfully antagonize each other and facilitate survival when administered together.

SPECIES OF THE TRIBES MIMEAE, NEISSERIEAE, AND STREPTOCOCCEAE WHICH CONFUSE THE DIAGNOSIS OF GONORRHEA BY SMEARS*

George G. De Bord, Ph.D., Washington, D. C.

FORTY years ago gram-negative diplococci from spinal fluids[1] or conjunctivitis[2] were considered meningococci. Such statements were refuted[3] at the time and since then it has been proved quite conclusively by other investigators[4-6] that diplococci other than the meningococci can cause a meningitis. Also during that time gram-negative diplococci in smears from conjunctivitis and vaginitis have been considered gonococci, although gram-positive diplococci which lose the Gram stain,[7, 8] lactose-fermenting rods which appear microscopically to be gram-negative diplococci,[9] and a species of the genus Neisseria other than the gonococcus in a rape case[10] have been reported. The investigations of Rossiter[11] on Samoan conjunctivitis were probably the first which proved definitely that a gram-negative diplococcus indistinguishable from the gonococcus in smear preparations was present in one type of conjunctivitis. This conjunctivitis had been diagnosed previously by smear preparations as gonorrheal despite the fact that venereal gonorrhea was not known on the island at that time.

The present investigation was undertaken to study the flora of conjunctivitis and vaginitis with special reference to the gram-negative diplococci. The cases studied included the newborn; children with conjunctivitis; girls of prepuberty age, both normal and those with varying degrees of vaginitis; and one case of conjunctivitis in an adult male.

EXPERIMENTAL

The medium used for isolation was a chocolate agar made from Difco proteose peptone No. 3 with 5 per cent citrated human blood. Later rabbit blood was substituted for human blood. Concentrated sugar solutions in distilled water were sterilized at 15 pounds pressure for fifteen minutes and added aseptically so that the final dilution in broth was 1 per cent. Acetone was used as the decolorant in the Gram stain. All media which were not used as they came from the autoclave were incubated for twenty-four hours before use. A sterile cotton swab was used to obtain the specimen which was streaked immediately over the plate. Each type of colony, with some duplications, was examined microscopically for gram-negative diplococci. The examinations for Neisseriae were made by the oxidase test with dimethyl-p-phenylenediamine. Many species, especially gram-negative rods, give this test, which makes it essential to examine the colonies microscopically and culturally for the correct determination of the species if gram-negative diplococci be present. This confirms the work of Gordon and McLeod[12] and Price.[13]

One hundred and forty-seven cases were studied. These included 41 patients with purulent conjunctivitis but did not include many other cases in which the eyes showed a mild discharge with a few intracellular or extracellular gram-negative diplococci in the direct smears and no species of Neisseria on the plates. Of the 41, 10 were infections with *Neisseria gonorrhoeae,* two cases showed *Neisseria catarrhalis,* and one showed *Neisseria fulva.*[14] The one adult male case showed *Neisseria intracellularis.* This species was shown to be serotype I when typed by Dr. Sara Branham of the U. S. Public Health Service. Twelve cases showed species of the tribe Mimeae,[14] of which two were *Herellea vaginicola* and *Colloides anoxydana.* Species of the remaining cases were not classified except to show that Neisseriae were not present.

Forty-nine cases showed vaginitis. Five were infections with *N. gonorrhoeae. N. fulva* was isolated once, three cases showed *N. catarrhalis,* and nine cases showed species of the tribe Mimeae, two of which were *Mima polymorpha* var. *oxidans* and one was *C. anoxydana.* The species of the remaining cases were not investigated further than to show that no species of the genus Neisseria was present.

In the group of 57 clinically normal cases, many showed an occasional intracellular or extracellular gram-negative diplococcus in the smear. One case showed *Neisseria gigantea,*[14] two showed *N. catarrhalis,* and 24 cases showed Mimeae of which two were *Mima polymorpha,* two were *M. polymorpha* var. *oxidans,* and one each of the species *H. vaginicola* and *C. anoxydana.*

DISCUSSION

The presence of gram-negative diplococci which were not Neisseriae was found by a systematic search. This was done by making a stained smear of every type, with some duplications, of colonies on the plate. Those species which appeared to be gram-negative diplococci were then studied culturally. The visual examination of the colonies is not sufficient because it is not possible to differentiate Mimeae, many forms of the gram-positive diplococci, and many forms of the diphtheroids by their colonial characters on plates. The three tribes,

Neisserieae, Streptococceae, and Mimeae, represented by the genera Neisseria, Mima, Herellea, Colloides, and the gram-positive diplococci which tend to lose the stain were found to be present in conjunctivitis and vaginitis. All these species are either true gram-negative diplococci or have forms which are gram-negative diplococci.

The presence of species of the genus Neisseria other than *N. gonorrhoeae* must be considered when diagnoses are made upon the basis of morphology. While these species are relatively less important when judged by the number which have been found in conjunctivitis and vaginitis, the possibility of their presence is one factor which must be considered when evaluating the reliability of smear examinations. The presence of *N. intracellularis* in the one case could have been detected only by cultural methods, thereby enhancing those methods in conjunctivitis. *N. intracellularis* and *N. fulva* were present in practically pure culture in both cases in which they occurred. The presence of *N. gigantea* could explain the statements in the literature that some cultures of the gonococcus showed large forms. The inability of *N. gigantea* to ferment sugars would not permit its presence to be recognized as a contaminant of cultures of *N. gonorrhoeae* because the fermentative reactions of *N. gonorrhoeae* would not be changed. Only the microscope would reveal the larger form. *N. catarrhalis* and *N. gigantea* were present in relatively few numbers in the cases in which they were found.

A second group of minor importance is the gram-positive diplococci which tend to lose the Gram stain. Schubert and Toenges[7] included certain streptococci in this group also. These species may be present in either vaginitis or conjunctivitis. The number of cases involved is low, and a systematic search by staining smears from many individual colonies on the plate is necessary to find those which decolorize, although they do predominate occasionally. The gram-positive diplococci which tend to lose the stain cannot be differentiated on the plates from those which do not decolorize because their colonial characters are the same and those which do not decolorize may be present in large numbers in vaginitis and conjunctivitis. The pairs of cocci which have decolorized are identical in appearance to the gonococcus when the size is the same.

The most important group is the tribe Mimeae. The prevalence of this tribe complicates the microscopic picture to such an extent that it is imperative to use cultural methods to obtain a true evaluation of the flora.

Since the microscopic picture of the species of the tribe Mimeae is identical to the genus Neisseria, except *N. gigantea,* all species of the tribe interfere in the diagnosis of gonorrhea by smears and *M. polymorpha* var. *oxidans* can interfere in the cultural method when tests are made presumptively by the oxidase test for the presence of Neisseriae.

The question of pathogenicity with these species cannot be answered categorically because Koch's postulates have not been fulfilled with the original animal, the human being. There are, however, several points indicating that they may be primary or secondary invaders. First, the diplococcal form is the more prominent at the primary isolation and the diplococcus/rod ratio[14] falls upon artificial cultivation. Second, extensive animal inoculations have not been done, but species having low diplococcus/rod ratios injected intraperitoneally in rela-

tively large numbers have been recovered with high ratios from the heart blood of the mice after death. Third, in conjunctivitis in the newborn where the data can be obtained, the infection arises very consistently from the fifth to the seventh day after birth and has persisted for as long as two months. Fourth, a change from an unbuffered silver nitrate solution to a buffered one used in the eyes at birth reduced the number of cases materially. Fifth, with all other supporting evidence lacking, pathogenicity might be assumed when only one species is present in the infection. This condition has not always been true, but in the cases with *N. intracellularis, N. fulva,* and some of the Mimeae in conjunctivitis, also with *N. fulva* and one case with *M. polymorpha* var. *oxidans* in vaginitis, the number of colonies of other species on the plate was negligible. It was noted that the species of Mimeae with greater fermentative powers, some of which have not been described, were more prevalent in conjunctivitis and vaginitis than those of the genus Mima which does not ferment carbohydrates. Proof is lacking whether this might be due to a greater pathogenicity or merely accidental circumstances. Whether any of these species are pathogenic or not, they constitute important sources of error which confuse the diagnosis of gonorrhea by smears.

As a result of the probable presence of one or more of the three groups, Mimeae, Neisserieae, gram-positive diplococci which tend to lose the stain, it is impossible to make logical comparisons between direct smears and cultures in conjunctivitis and vaginitis. In the smears the gram-negative diplococci of the three groups are not differentiated from the gonococcus, rods and filaments cannot be used as a basis for determining the presence of the pleomorphic Mimeae, and gram-positive diplococci would not prove whether it was a species that tended to lose or retain the stain. There is, therefore, no criterion which would indicate the presence of these species in stained preparations, and it would be entirely possible for a diagnosis of gonorrhea to be given from a smear preparation in conjunctivitis or vaginitis, even though a pure culture of either Mimeae or gram-positive diplococci which tend to lose the stain was present. The Mimeae, with the exception of *M. polymorpha* var. *oxidans,* and the gram-positive diplococci which tend to lose the stain would not be detected by the oxidase test on the plate, and their presence could be determined only by a systematic search for gram-negative diplococci.

The statement that the gonococcus is difficult to grow may be explained by the presence of one or more of the tribes, Mimeae, Neisserieae, Streptococceae, which show as gram-negative diplococci in stained preparations but could not be detected readily on the cultural plate unless a systematic search were instituted for them. Neither the presence of gram-negative diplococci in a stained smear nor the oxidase reaction on a plate proves the presence of *N. gonorrhoeae.*

SUMMARY AND CONCLUSIONS

From the 147 cases of conjunctivitis, vaginitis, and normal vaginas, Mimeae were isolated forty-five times; gram-positive diplococci, which tend to lose the stain, six times; and Neisseriae, excluding the gonococcus, eight times. The total, 59, represents about 40 per cent in which real or apparent gram-negative diplococci were present which can be mistaken easily for *Neisseria gonorrhoeae.*

As a result of this investigation it is felt that the identification of *N. gonorrhoeae* by smears in conjunctivitis or vaginitis is not justified.

Appreciation is expressed to Dr. George C. Ruhland, Health Officer of the District of Columbia, who has made this investigation possible by his cooperation and interest. Acknowledgments are due Dr. H. H. Leifer for his many courtesies and collaboration.

EFFECT OF ETHYL ALCOHOL INTOXICATION ON THE DEVELOPMENT OF LOCAL INFLAMMATORY REACTIONS IN THE RABBIT

R. H. Rigdon, M.D., Memphis, Tenn.

Pickrell[1] in 1938 reviewed the literature on the effect of intoxication on infection and immunity. He states that "while it is rather generally agreed that infected intoxicated animals die sooner than similarly infected, nonintoxicated ones, it is fair to say that very few of the studies have been adequately controlled. . . . No satisfactory explanation has as yet been established for any resistance lowering effect that alcoholic intoxication may exert."

From an experimental study made upon a large series of rabbits, Pickrell[1] concludes that "alcoholic intoxication maintained at the point of stupor, de-

*From the University of Tennessee, Department of Pathology, Memphis.

Received for publication, August 12, 1942.

stroys resistance to pneumococcal infection. . . . The loss of resistance to infection appears to be due to the fact that intoxication profoundly inhibits the vascular inflammatory response. . . . In the absence of capillary dilatation and margination of the leucocytes, leucocytic emigration at the site of infection is negligible. . . . In what manner intoxication acts to prevent the usual inflammatory alterations in the capillaries is at present obscure but that it does so is clearly evident.''

Cressman and Rigdon[2] studied capillary permeability and inflammation in narcotized rabbits and found that ''capillary permeability in areas of inflammation is altered in rabbits narcotized with alcohol or ether, as demonstrated by the localization and concentration of trypan blue. . . . There is also a marked diminution in the number of leucocytes in the areas of inflammation in the skin in the narcotized rabbits.'' The observations of Cressman and Rigdon, therefore, are similar to those of Pickrell; however, neither have explained adequately the mechanism of this phenomenon.

Rigdon and associates have recently demonstrated that capillary permeability and inflammation in the skin of the rabbit may be affected by changes in the blood pressure; that is, when the pressure is abnormally low, the macroscopic and microscopic changes characteristic of inflammation either fail to appear or they are markedly decreased in the skin. It has been suggested that the peripheral vessels in the skin become constricted following the loss of blood,[3] sectioning of the cervical portion of the spinal cord,[4] and in staphylococcus septicemia in the rabbit.[5] The blood apparently does not circulate in the small blood vessels in the skin of these animals since the skin becomes pale, cold, and clammy. This absence of a normal circulation apparently may account for the absence of a leucocytic reaction about various irritants when they are injected intradermally into the animals.

Alcohol in large amounts will produce a lowering of the blood pressure.[6] This change in the pressure apparently may result from the effect of the alcohol on the heart. In view of our present knowledge of the effect of lowered blood pressure on the development of an inflammatory reaction in the skin of the rabbit, it seems important to restudy the effect of ethyl alcohol intoxication on the development of the inflammatory reaction in the skin of the rabbit. Observations are also made on the development of the inflammatory process in the rabbits' intestines since the circulation here apparently remains intact while that in the skin may become either markedly decreased or even absent in severe intoxication.

METHODS AND MATERIALS

Adult rabbits, varying from 1.5 to 2.5 kg. are used. The skin over the abdomen is carefully shaven twenty-four hours or longer before the experiments are begun. A 20 per cent dilution of ethyl alcohol is given through a small catheter into the stomach. Each rabbit is given 80 c.c. of alcohol, and smaller quantities are given subsequently if necessary to obtain complete anesthesia. The blood pressure is recorded at intervals from the carotid artery.

Four-tenths cubic centimeter of a twenty-four-hour broth culture of staphylococci are injected intradermally usually six, four, and two hours before the rabbits are killed. An incision is made in the abdominal wall; the intestines are exposed, and 0.4 c.c. of the broth culture is injected into the wall of the colon

of some of these rabbits. The animals are killed from two to six hours following the injection of the staphylococci. The areas of tissue injected with the cultures are removed and fixed immediately in a 10 per cent solution of formalin. Paraffin sections are prepared and they are stained with hematoxylin and eosin.

To study the effect of alcohol intoxication on capillary permeability, the abdomen of a group of rabbits is exposed to infrared radiation.* The light is placed 10 inches away from the skin. Immediately following the application of the light, 10 c.c. of a 0.2 per cent solution of trypan blue are given intravenously. This dye localizes and concentrates in the skin around the margin of the irradiated areas in normal rabbits and also in the coils of intestines that lie immediately beneath the portion of abdominal wall that is irradiated. The blood pressure is recorded from the carotids in these animals.

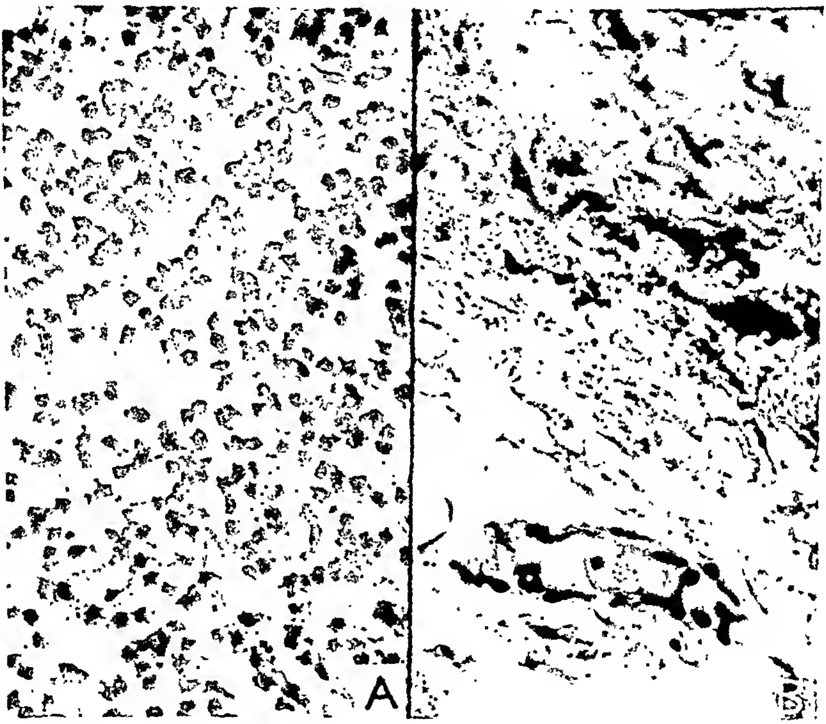

Fig. 1.—*A*, Rabbit 1192. Normal rabbit, 0.4 c.c. of twenty-four-hour broth culture injected intradermally six hours before section removed. There is a diffuse infiltration of polymorphonuclear leucocytes in the corium. *B*, Rabbit 1213. Rabbit given 70 c.c. of 20 per cent alcohol at 8:40 A.M.; blood pressure 80 at 9:50 A.M.; 0.4 c.c. broth culture of staphylococci injected intradermally at 10:20 A.M.; blood pressure 60 at 1:00 P.M., and 40 at [illegible] d at 4:30 P.M. The corium is infiltrated with bacteria; but there are n [illegible] the area.

As a control for this experiment on capillary permeability one group of rabbits is given pentobarbital intravenously; a second group is unanesthetized except for using 1.0 c.c. of a 1.0 per cent solution of novocaine in the neck before putting the cannula into the carotid artery. Infrared irradiation and trypan blue are given in a manner similar to that in the experimental group. The presence or the absence of trypan blue in the skin is recorded. The rabbits are killed at intervals varying from thirty minutes to four hours following the injection of the dye.

*The infrared lamp is supplied by the Burdick Company of Milton, Wisconsin. It is type Z-70, Zoalite.

LOCALIZATION OF POLYMORPHONUCLEAR LEUCOCYTES ABOUT STAPHYLOCOCCI INJECTED INTRADERMALLY IN NORMAL AND INTOXICATED RABBITS

Five normal rabbits are injected intradermally with the broth culture of staphylococci. Edema and hyperemia develop around the site of the injection. Polymorphonuclear leucocytes infiltrate the tissues within a period of two hours. The number of leucocytes rapidly increase during the subsequent four hours (Fig. 1*A*).

Sixteen rabbits are given alcohol. When completely anesthetized, a cannula is put into the carotid artery and the pressure is recorded. It is usually decreased at this time from the normal of 100-120 mm. Hg. The pressure may continue to fall or it may be necessary to give a second dose of alcohol in order to lower the pressure. The bacteria are not injected until the pressure reaches a level of approximately 70 mm. Hg or even less. The macroscopic reaction in the skin apparently is proportional to the level of the blood pressure. When the pressure is approximately 60 mm. Hg, the edema and hyperemia are markedly reduced. There is essentially no macroscopic reaction when the pressure is either 50 mm. or less. Histologically the number of polymorphonuclear leucocytes are proportional to the level of the blood pressure. When the pressure is either 50 mm. Hg or less, there are essentially no polymorphonuclear leucocytes about the clumps of bacteria (Fig. 1*B*).

LOCALIZATION OF POLYMORPHONUCLEAR LEUCOCYTES ABOUT STAPHYLOCOCCI INJECTED INTO THE WALL OF THE COLON OF RABBITS INTOXICATED WITH ETHYL ALCOHOL

In the previous experiments it was shown that polymorphonuclear leucocytes fail to localize and to concentrate about groups of staphylococci in the skin of rabbits intoxicated with ethyl alcohol when the blood pressure is abnormally low. A group of six rabbits are given a quantity of alcohol equal to that given to the animals in the preceding experiments. Staphylococci are injected into the wall of the colon and into the skin of these rabbits. The blood pressure is recorded during a period of four to six hours subsequently. When the pressure is abnormally low, there are no macroscopic evidences of inflammation in the skin. There are macroscopic evidences of inflammation, however, in the intestines about the point of injection of the bacteria. Histologically, there are no polymorphonuclear leucocytes about the bacteria in the skin, although many leucocytes have infiltrated the wall of the intestines about the point of injection of the bacteria (Fig. 2).

The results of this experiment indicate that intoxication per se is not the direct cause of the failure of leucocytes to localize and to concentrate about collections of staphylococci. If the bacteria are in the wall of the colon, the leucocytes localize and concentrate in a manner similar to that in an unintoxicated animal. Furthermore, the results suggest that the reaction in the skin is directly affected by the level of the blood pressure. When the pressure is abnormally low, the skin becomes pale, cold, and clammy, indicating a disturbed circulation in the peripheral vessels. The blood flow through the intestine of the same rabbits apparently is not similarly decreased. Polymorphonuclear leucocytes continue to localize and to concentrate about staphylococci as they do in an unintoxicated rabbit.

OBSERVATIONS ON CAPILLARY PERMEABILITY IN THE SKIN AND INTESTINES OF INTOXICATED RABBITS

In unpublished experiments it has been found that infrared radiation when applied to the skin of a normal rabbit for five minutes produces both macroscopic and microscopic evidences of inflammation. Similar pathologic changes also occur in the wall of the intestines. Trypan blue injected intravenously into these rabbits localizes and concentrates in both the treated areas of skin and in the intestines.

Fig. 2.—Rabbit 1213. Same rabbit as shown in Fig. 1 *B*. 0.4 c.c. of the broth culture of staphylococci was injected into the wall of the colon six hours before the rabbit was killed. There are many leucocytes infiltrating the area.

Fig. 3.—Rabbit 1294. Rabbit given 80 c.c. of alcohol at 9:30 A.M. Blood pressure 80 at 10:15, 60 at 10:30, 35 at 11:05, and 30 at 11:10. Infrared light is applied for five minutes to skin of abdomen in area outlined with India ink at 11:20; 10 c.c. of trypan blue are given intravenously immediately following the light. At 12:00 there is no trypan blue in the skin, but the portion of intestines immediately beneath the treated area of skin is dark blue in color.

In the study of the effect of alcohol intoxication on capillary permeability six rabbits are given alcohol. The blood pressure is recorded. When it is abnormally low (approximately 50 mm. Hg), the infrared lamp is placed over the abdomen for a period of five minutes. The macroscopic reaction in the skin is insignificant. The animals are given trypan blue intravenously immediately following the irradiation. A minute amount of the dye localizes in the skin of some of the rabbits; however, no dye localizes in the skin of the majority of the animals (Fig. 3). The coils of intestines beneath the site of application of the light becomes blue in every rabbit (Fig. 3).

Three rabbits are given pentobarbital in a quantity sufficient to produce complete anesthesia. The blood pressure is recorded from the carotid. It is 80, 80, and 85 in each of the three animals. Infrared is applied to the abdomen. Trypan blue is injected intravenously. This dye localizes around the periphery of the area of skin treated and in the underlying portion of the intestines. The normal blood pressure in a second group of three rabbits is determined before the infrared irradiation is applied. Local anesthesia is used (1.0 c.c. of 1 per cent novocaine) for the operative procedure necessary to put the cannula into the carotid. The pressure in these three rabbits is as follows: 90, 90, and 95. Trypan blue localizes in the skin and in the intestines of each of these rabbits. These two groups of rabbits are controls for the above experiment and show that this dye will localize in the skin provided the pressure has not reached the abnormally low level of 50 mm. Hg.

The results of this experiment show that trypan blue may fail to localize and to concentrate about areas of injury in the skin of rabbits intoxicated with ethyl alcohol; however, this dye always localizes and concentrates in the intestines of each of these intoxicated animals.

DISCUSSION

The results of this experiment confirm the observations of Pickrell,[1] and Cressman and Rigdon[2] that alcohol intoxication may completely inhibit the development of an inflammatory reaction in the skin of the rabbit. The data suggest that this phenomenon does not result directly from the effects of alcohol upon either the leucocytes or the local blood vessels. The circulation in the skin apparently is markedly reduced in intoxicated rabbits, and as a consequence of this trypan blue and polymorphonuclear fail to localize in the skin of these animals. The fall in blood pressure, the rapid rate of the respirations, the cold, clammy skin all indicate that a diminution has occurred in the blood flow through the peripheral vessels.

The circulation in the intestinal tract during intoxication is not affected similarly to that of the skin. Capillary permeability here is increased, and leucocytes localize about foci of bacteria the same as they do in a normal rabbit. Edmunds and Gunn[6] state that large quantities of alcohol lower the blood pressure by weakening the vasoconstrictor centers and the heart muscle. In a series of experiments it has been shown that a leucocytic reaction fails to occur in the skin of rabbits with a low blood pressure.[3-5] The results of the present experiment are consistent with these observations upon capillary permeability and the development of local inflammatory reactions.

SUMMARY

Polymorphonuclear leucocytes fail to localize and to concentrate about staphylococci in the skin of rabbits intoxicated with ethyl alcohol when the blood pressure is abnormally low.

Leucocytes concentrate about staphylococci injected into the colon of the same intoxicated animal. This variation in the reaction in the skin and the colon may result from the lowered pressure produced by alcoholic intoxication. When the pressure is lowered, the skin becomes cold and clammy, suggesting that the peripheral circulation is markedly decreased or completely inhibited. The circulation in the intestines apparently remains intact.

Capillary permeability as shown by the localization of trypan blue following an intravenous injection is absent in areas of injured skin in rabbits intoxicated with ethyl alcohol. It is present, however, in the injured areas of intestines of the same intoxicated rabbit.

ALCOHOLIC CIRRHOSIS OF THE LIVER*

A Clinical and Pathologic Study of 356 Fatal Cases Selected From 12,267 Necropsies

J. D. Kirshbaum, M.D.,† and Norman Shure, M.D.
Chicago, Ill.

SINCE 1826 when Laënnec adequately described cirrhosis of the liver, it has been observed and recognized, without much difficulty, both clinically and pathologically. However, the observation of increased connective tissue stroma in livers of varying weights, sizes, shapes, colors, and histologic architectures has provoked a certain amount of confusion in the nomenclature. As a result, in common usage today are such terms as atrophic cirrhosis, hypertrophic cirrhosis, multilobular cirrhosis, portal cirrhosis, biliary cirrhosis, Laënnec's cirrhosis, Hanot's cirrhosis, hobnail liver, alcoholic cirrhosis, gin drinker's liver, toxic cirrhosis, Wilson's disease, Banti's disease as well as many others.

Broadly, cirrhosis of the liver is merely a condition in which the connective tissue stroma is increased. Any stimulus to fibroblastic proliferation may eventually produce a well-marked cirrhosis. Mallory[1] lists four conditions under which the fibroblasts of the liver stroma proliferate:

1. To replace any which have been destroyed as a result of abscess, infarcts, syphilis, colon bacillus infection, etc.
2. Following mechanical injury (stretching), as in chronic passive congestion and bile stasis.
3. To organize fibrin, as for thrombi in sinusoids.
4. To form stroma for islands of regenerated liver cells and for tumor nodules.

It is apparent that the number of agents which may initiate the ultimate picture of cirrhosis is very large and for that reason the question "Is cirrhosis of the liver a disease entity?" is often raised.

The great majority of cirrhotic livers fall into four major groups and can be classified as follows:

1. Toxic cirrhosis
2. Biliary cirrhosis
   - a. Obstructive
   - b. Infectious
3. Pigment cirrhosis
4. Alcoholic cirrhosis
   - a. Periportal cirrhosis
     - I. Atrophic form (small liver)
     - II. Hypertrophic form (large liver)

*From the Department of Pathology, Woodlawn Hospital, and Cook County Hospital, and the Department of Medicine, University of Illinois.

Received for publication, August 13, 1942.

b. Fatty cirrhosis (hypertrophic form)
(Large amount of fat and little or no fibrosis)

Though this classification does not include every type of sclerotic liver known, many of which are exceedingly rare, it does encompass the commonly known types and does, more or less, conform to the nomenclatures and classifications of other investigators.[3-5]

Toxic Cirrhosis.—This occurs after necrotizing lesions of the liver parenchyma and may follow acute infections, such as acute yellow atrophy, repeated attacks of catarrhal jaundice, Weil's disease; or it may be the result of the ingestion of such drugs as cinchophen or arsenic.

Biliary Cirrhosis.—The obstructive type is associated with obstruction of the biliary passages by stone or tumor; the infectious type begins as an ascending cholangitis. These two types frequently co-exist.

Pigment Cirrhosis.—In hemachromatosis, often called "bronzed diabetes" because of the association of the typical coloring of the skin with glycosuria, the cirrhosis of the liver is merely one of the manifestations of a generalized condition. Either as a result of the liver-cell necrosis or as a result of the irritation of the iron pigment collected around the periphery of the lobule, there is an active macrophage and fibroblastic proliferation from the periportal connective tissue.

Alcoholic Cirrhosis.—The term "alcoholic cirrhosis" is an arbitrary one and, perhaps, not a very good one. To limit the diagnosis of alcoholic cirrhosis to those cases in which a definite history of chronic alcoholism is given, as Boles and Clark[6] do in their report of autopsy material from the Philadelphia General Hospital, we feel is too strict. The fatty cirrhosis is conceded by most investigators to be of alcoholic origin. The Laënnec cirrhosis is the type that has been called "alcoholic" for over a hundred years. There is a third type of alcoholic liver, the so-called "hypertrophic fatty form." It is large, tense, and loaded with fat. The liver is swollen and greasy; it may appear granular due to the subsurface lobules being distended with fat (see Fig. 1). This type of liver usually shows little or no sign of fibrosis and is observed in young people between 30 and 40 years of age. This form is usually larger than normal, smooth in contour, and weighs about 3,000 Gm. It may, however, be lobulated and nodular, depending upon the amount of connective tissue present. On cutting it is found to be greasy yet resistant.

Periportal cirrhosis is the typical portal cirrhosis which was described by Laënnec. The liver may be large or small, smooth or granular. The thought that it is larger in its early stage and becomes atrophic has been discarded. The noxious agent which initiates the cirrhosis is thought to enter the liver by way of the portal blood stream. The adjacent liver cells are damaged and connective tissue proliferation results. The newly proliferated connective tissue may become condensed and sclerotic, producing the small, hard, hobnail liver. Because of obstruction to the portal circulation, ascites develops, the spleen becomes engorged, the mucosa of the gastrointestinal tract becomes congested, and attempts at the establishment of a collateral circulation to compensate for the decreased venous bed are apparent. The presence of a caput medusae on the anterior abdominal wall and the frequent hemorrhages resulting from rupture of dilated

and varicose veins in the lower esophagus are typically products of this common type of cirrhosis.

The association of cirrhosis of the liver with alcohol is still a debatable point. Attempts at the production of cirrhosis experimentally with alcohol have not been successful, though it is believed that alcohol may be an accessory factor in the production of cirrhosis due to bacterial infection. In attempting to produce experimental cirrhosis by the use of agents which might possibly exist as

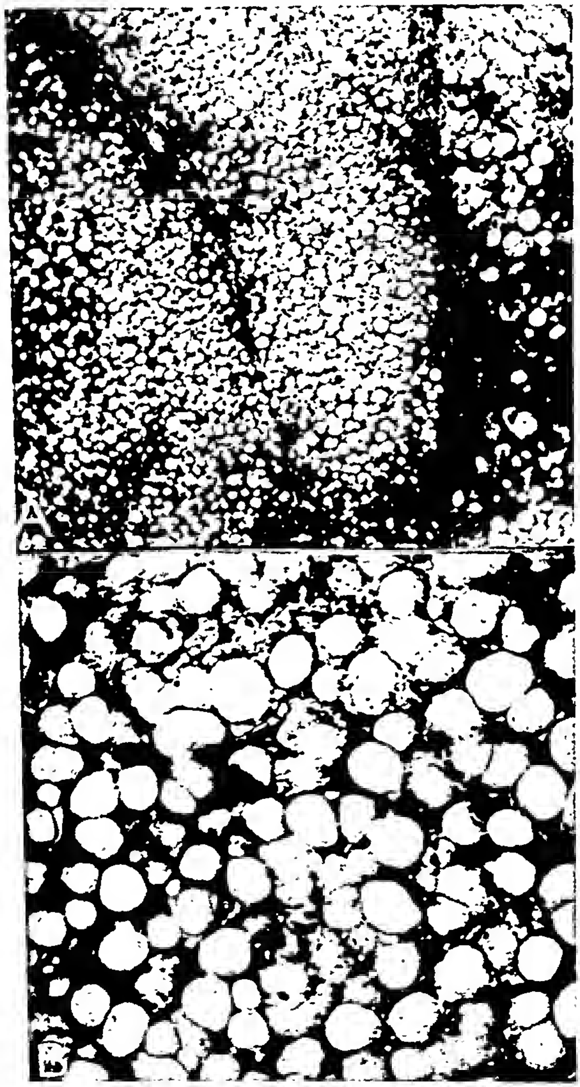

Fig. 1.—Photomicrograph shows (*A*) low-power field from a hypertrophic fatty liver. Note abundance of fat and very narrow periportal septa. *B*, High-power magnification. The liver cells contain large fat droplets and the nuclei are displaced to the periphery.

impurities in alcoholic beverages, Mallory was successful only with the use of copper. The recent work of Connor[7, 8] on the development of fatty livers in chronic alcoholism and the development of cirrhosis in fatty livers is interesting. Following the work of Himwick and Fazekas on liver metabolism in diabetes, Connor is of the opinion that in alcoholics there is a similar deficient carbohydrate

utilization. Because of the action of alcohol as a cell and tissue toxin there is a definite deficiency in carbohydrate metabolism and fat oxidation. In starvation or a carbohydrate-poor diet, such as is common in many alcoholics, sugar is withheld from the metabolic cycle. It has been shown that in experimental diabetes, in starvation, and in alcoholic intoxication the respiratory quotient of the liver is lower than that of the body as a whole or when fat alone is being consumed. In alcoholics it is probable that a condition similar to that of diabetes is produced and because of insufficiently utilized carbohydrates there is a piling up of unoxidizable fat within the liver cell.

The development of cirrhosis in a fatty liver, Connor states, is the result of pressure of the liver cells distended with fat upon the sinusoids. The sinusoids become collapsed and a thickening of the wall of the sinusoids is an early feature. The thickening of the walls with the formation of collagenous material promotes a reticulum production about the liver cells which have degenerated as a result of anoxemia. Fibroblastic proliferation follows. The interlobular stroma likewise is often stimulated to proliferate by the mechanical pressure of the distended liver lobules. Connor believes that the transition from a fatty liver to one of cirrhosis with very little or no fat is a result of the decreased carbohydrate intake an alcoholic assumes when his liver begins to provoke gastrointestinal symptoms.

Our material consists of the necropsy records of 356 cases of fatal alcoholic cirrhosis occurring in 12,267 consecutive autopsies performed at the Cook County Hospital from January 1, 1929, to July 1, 1939, inclusive.

Incidence.—There were 356 cases of cirrhosis, constituting 2.83 per cent of all our cases. This corresponds to Mallory's report of 2.2 per cent, but is higher than the incidence reported by Menne and Johnson,[9] or Evans and Gray.[10] It is somewhat lower than the incidence in Japan reported by Suzuki.[11] The yearly variation of cirrhosis of the liver, we believe, is significant (see Table I). Starting from a high level for 1929, there is a steady drop, reaching a low point in 1932. From 1933 there is a steady staggered rise. Though we are very reluctant to conclude from post-mortem records that a disease which may last ten or twenty years before resulting in death was less prevalent during a seven-year period, we cannot help noticing the regularity of the curve of yearly incidence. It can hardly be a coincidence that the curve is downhill until 1932 and has

TABLE I

INCIDENCE OF CIRRHOSIS

YEAR	AUTOPSIES	CIRRHOSIS	PER CENT
1929	955	28	2.93
1930	986	21	2.13
1931	1,114	25	2.24
1932	1,207	21	1.74
1933	1,192	31	2.60
1934	1,300	35	2.69
1935	1,176	40	3.40
1936	1,242	38	3.06
1937	1,167	52	4.45
1938	1,327	45	3.39
1939 (6 months)	601	20	3.35
Total	12,267	356	Avg. 2.83

been rising since. This peculiar level of incidence of a decrease until the year of the repeal of the prohibition amendment, followed by a steady rise, corresponds to the results of Evans and Gray[10] in their report of 17,874 autopsies at the Los Angeles General Hospital, and those of Boles and Clark[5] in their report of 4,000 autopsies at the Philadelphia General Hospital as well as the opinion of Rowntree,[12] who collected statistics from several institutions and public health agencies.

Sex.—Of our cases 244, or 68.5 per cent, were males, and 112, or 31.5 per cent, were females. Compared to our normal ratio of male to female autopsy material, which is two to one, we can conclude that cirrhosis occurs about twice as frequently in men as in women. These findings correspond with those of American observers, but are at odds with those of Japan and France. Suzuki,[11] in a report of 21 cases of cirrhosis out of 596 autopsies performed at the Kumamoto Medical College, found 19 males and 2 females. Paraf and Klotz[13] in a two-year period found that out of 1,030 females hospitalized at the Hôpital de Paris there were 23 cases of cirrhosis, or 2.2 per cent. In the same period, of 1,311 male admissions only 6, or 0.53 per cent, showed cirrhosis of the liver. The comparison, more than four times as frequent in females, is interesting and may open the way for a discussion on alcoholism in the French woman. The relation of sex to the occurrence of jaundice and ascites is noteworthy. The males in our group, though constituting 68.5 per cent of all our cases, comprised 76.4 per cent of all patients who had ascites alone. Conversely, the females comprised 39.5 per cent of all the cases having jaundice alone, somewhat above the figure for percentage of women having cirrhosis (see Table III).

Race.—There were 308, or 85.9 per cent, white and 50, or 41.1 per cent, colored persons in our series. Sex appeared to have no relation to race in our series, the male to female proportions being the same in both races. In our institutions where 35.8 per cent of our autopsy material consists of colored persons, the marked discrepancy of incidence is noteworthy.

TABLE II

DISTRIBUTION OF SEX AND RACE IN VARIOUS AGE GROUPS

	UNDER 30	31-40	41-50	51-60	61-	TOTAL
Male	1	22	68	89	64	244
Female	12	28	36	22	14	112
Colored	5	11	14	13	7	50
White	8	39	90	98	71	306
Total	13	50	104	111	78	356
Per cent	3.6	14.1	29.2	31.2	21.9	

Age.—Our youngest patient was 16 years; our oldest, 77 years. Thirteen, or 3.6 per cent, of our cases were under 30 years; 60, or 14.1 per cent, were 31 to 40; 104, or 29.2 per cent, were 41 to 50; 111, or 31.2 per cent, were 51 to 60; and 78, or 21.9 per cent, were over 60. The distribution of the various age groups in relation to sex and race can be seen in Table II. It appears that though 76, or 67 per cent, of the females were under 50, only 91, or 37 per cent, of the males were in the corresponding age group. The majority (64 per cent) of the males fall into the 41 to 60 age group while 57 per cent of the women are in the 31

to 50 age group. We believe that the increased incidence of cirrhosis in younger women in our series indicates mortality rather than pure incidence. Women with cirrhosis die at a younger age than do men. This is bolstered by the face that out of 13 cases in our youngest age group (under 30) 12 were women.

History of Alcoholism.—In 12 of our cases there was no clinical history available. Of the remaining 344 a definite admittance of chronic alcoholism was obtained in 144, or 41.9 per cent. We consider this to be far below the true incidence of indulgence in alcohol of the patients constituting our material. In obtaining the history of illness from the patient, the question of alcoholism is merely a part of the general survey of his habits. Unless a condition similar to cirrhosis or neuritis is suspected, the intern taking the history paid no more attention to the patient's temperance habits than he did to the amount of coffee or tea he drank or to the number of cigarettes he smoked. When a patient enters with obvious signs of intestinal obstruction, in diabetic coma, or with a perforated duodenal ulcer, as a great deal of our material does, the intern, with some justification, is not concerned with the patient's social habits and certainly does not anticipate the statistical survey which may result from his history. However, with the use of mimeographed forms for detailing a patient's history, our material is becoming more accurate and the only error remaining in a history of alcoholism will be that of the patient's reluctance in admitting it.

TABLE III

DISTRIBUTION OF JAUNDICE AND ASCITES

	JAUNDICE	ASCITES	JAUNDICE AND ASCITES	TOTAL JAUNDICE	NEITHER JAUNDICE NOR ASCITES
Male	26	65	87	113	66
Female	17	20	39	56	36
White	37	72	114	151	83
Colored	6	13	12	18	19
Under 30	4	1	3	7	5
31-40	8	7	21	29	14
41-50	13	21	46	59	24
51-60	16	31	35	51	29
Over 60	2	25	21	23	30
Total	43	85	126		102
Per cent	12.1	23.9	35.4		28.6

Jaundice and Ascites.—Jaundice occurred in 169, or 47.7 per cent, of our cases, and ascites in 211, or 59.2 per cent. The incidence of jaundice and ascites in relation to age, sex, and race is shown in Table III. It has already been pointed out that females are more likely to have jaundice without ascites and males are more likely to have ascites without jaundice. There are other significant facts apparent from Table III. Though the youngest age group constitute only 3.6 per cent of all the cases of cirrhosis, they comprise 9.3 per cent of all those having jaundice alone; the oldest age group, which make up 21.9 per cent of all our cases, constitute only 4.6 per cent of all cases of jaundice occurring alone. The incidence of jaundice alone shows a steady decrease as the age increases, while the occurrence of ascites alone increases with age. The combination forms (jaundice with ascites and neither jaundice nor ascites) seem to produce

opposing parabolic curves. Jaundice plus ascites is most prevalent in the middle age groups and is low in the extreme age groups: absence of both jaundice and ascites is lowest in the middle groups and highest in the extreme.

The ascites is produced by transudation of fluid from the mesenteric veins, a part of the portal system, as a result of obstruction and reduction in the size of the vascular bed. Our results of the occurrence of jaundice are at some variance with the common conception that jaundice does not occur frequently in this type of cirrhosis. Boyd says, in connection with the disturbed hepatic architecture seen, "Indeed it is to be wondered that jaundice is not a more marked feature in portal cirrhosis." Jaundice, with or without ascites, is most common in younger people. It occurred in 53.82 per cent of those under 30 years; 58 per cent of those 31 to 40; 56.7 per cent of those 41 to 50; 45.9 per cent of those 51 to 60; and 29.47 per cent of those over 60. We may interpret these results to indicate that jaundice is a late manifestation, late in the life of the disease rather than in the life of the patient. We may assume by the comparatively low incidence of jaundice in the older age group that these people survived because they did not develop jaundice, and that if they had developed jaundice at an early age they would have died at the earlier age to correspond with our increased incidence in the younger age groups.

Jaundice in cirrhosis is not due merely to compression of the bile ducts by connective tissue. It is probably due to the inability of the liver cells to excrete the bile pigment which is sent to the liver in normal amounts. The liver cells are abnormal, both early in the disease when the noxious agent which provokes connective tissue proliferation attacks them, and late in the disease when the increased connective tissue obstructs the sinusoids so as to produce venous stasis and subsequent anoxemia of the liver cells.

Esophageal Varices.—In our series there were 103 cases of esophageal varices constituting 28.6 per cent of the total (76 males; 27 females). Of these, in 33, or 32 per cent, of the number of cases with dilated and varicose esophageal veins, there were definite bleeding points noted. In many of these a massive hemorrhage was the immediate cause of death. This hardly corresponds with the report of McIndoe,[14] who notes a mortality due to hemorrhage of 50 per cent in 26 cases of advanced cirrhosis.

The incidence of esophageal varices in relation to age, as seen in Table IV, shows an increase with age until the 60-year-old group is reached, and is followed by a marked decrease. In examining the incidence of ruptured esophageal veins in the different sexes, we noted that though the females comprise 26 per cent of the total cases of varices and 20 per cent of those which have not ruptured, they constitute 39.3 per cent of the ruptured group. In addition, of the 27 women who had esophageal varices, 13, or 48.1 per cent, ruptured as compared to 20 of 76, or 26.3 per cent, of the men. This seems to indicate that though the presence of esophageal varices is somewhat less common in women than it is in men, when they do occur in women they are more likely to rupture.

Operations to produce more abundant anastomoses between the portal and systemic venous systems have been done repeatedly since 1889 when von der Meulen performed the first at the suggestion of Talma. After Morison performed the first successful one in 1895, varying reports of success have been

TABLE IV

ESOPHAGEAL VARICES IN RELATION TO SEX AND AGE

AGE	VARICES	MALE	FEMALE	TOTALS	
Under 30	Unruptured	0	1	1	3
	Ruptured	0	2	2	
31-40	Unruptured	6	1	7	13
	Ruptured	1	5	6

Over 60	Unruptured	15	1	16	19
	Ruptured	3	0	3	

reported by Monprofit, Bunge, White, Mayo, and Tempsky. In a recent paper Grinnell[15] lists 23 cases in which 22 were followed up after the performance of surgery. He reports 9 per cent symptom free after a period of years; 32 per cent improved and 59 per cent unimproved. With an operative mortality of 27 per cent these figures are not encouraging.

TABLE V

BLOOD PRESSURE AND WEIGHT OF HEART

AGE	SYSTOLIC BLOOD PRESSURE					WEIGHT OF HEART		
	UNDER 120	120-140	140-160	160-180	OVER 180	UNDER 325 GM.	325-400 GM.	OVER 400 GM.
Under 30	4	4				13	0	0
31-40	12	11	7	2	4	23	10	11
41-50	28	23	20	4	4	48	35	21
51-60	29	16	25	15	7	37	29	31
Over 60	13	18	11	9	7	29	17	25
Total	86	72	63	30	22	170	91	88

Blood Pressure.—It is often stated that a persistently low arterial blood pressure is maintained in cirrhosis of the liver. Our material included cases of hypertension as well as those of hypotension. Of 273 cases in which a record of the blood pressure was available there were 158 in which the systolic arterial pressure was under 140 and 115 in which it was above 140. Table V indicates the distribution of the arterial tension in relation to the age of the individual; the weight of the hearts, an increase which often corroborates the clinical finding of hypertension, is also shown. In 179 cases the heart showed anatomical evidences of hypertrophy. There seems to be no indication that cirrhosis of the liver per se has any marked effect on the cardiovascular system.

Weight of the Liver.—In the 343 cases we recorded, 214, or 62.4 per cent, might be termed "hypertrophic"; 129, or 37.6 per cent, were "atrophic," and 66, or 19.2 per cent, were of the hypertrophic fatty form. The comparison of the incidence of the various liver weights in each age group is interesting (see Table VI).

TABLE VI

WEIGHT OF THE LIVER

AGE	UNDER 1,000 GM.	1,000-1,500 GM.	1,500-3,000 GM.	OVER 3,000 GM.	TOTAL
Under 30	1	2	7	3	13
31-40	4	11	28	7	50
41-50	8	28	54	13	99
51-60	5	36	55	10	106
Over 60	13	25	34	3	75
Total	31	98	178	36	343

Weight of the Spleen.—In one of our series a splenectomy had been done long before admission to the hospital; in four others the weight of the spleen was not recorded. Of the recorded weights the smallest was 50 Gm. and the largest was 2,045 Gm. Except for 12 the spleens were unanimously enlarged. Table VII shows the weights of the spleen in relation to sex and race. There is no marked difference in the sexes. In the races, however, there is a great variation. In 12 of 50 colored persons (24 per cent) the spleen weighed less than 100 Gm. as compared to 4 per cent in white patients. Sixty-two per cent of the colored persons had spleens weighing less than 200 Gm., while in 52.6 per cent of the whites it weighed more than 300 Gm. It is well known that the normal weight of the spleen in colored persons is less than in white, the discrepancy, however, in our results can hardly be explained on that basis. The abnormal constitution of the red blood cell in the Negro race is shown in its peculiar tendency toward sickling. We can only infer, at this point, that the marked difference in the weights of the spleens in our colored patients as compared to that in the white is merely another manifestation of the constitutional difference in the hematopoietic tissues of the Negro race.

TABLE VII

WEIGHT OF THE SPLEEN

WEIGHT	UNDER 100	100-200	200-300	300-400	400-600	OVER 600	TOTAL
Colored	12	19	7	4	8	0	50
White	12	65	66	62	68	28	301
Male	12	56	53	47	53	20	241
Female	12	28	20	19	23	8	110
Total	24	84	73	66	76	28	351

Pancreas.—There was no marked variation in the weights of the pancreas except in isolated cases, one weighing as much as 230 Gm., another as little as 30 Gm. In 129, or 36.2 per cent, of our cases, a well-marked fibrosis was noted.

There were five cases in which calculi were found in the pancreatic duct. This pancreolithiasis may be considered secondary to the cirrhotic condition of the pancreas. Cirrhosis was noted in 50 per cent of all cases of pancreolithiasis encountered in our necroptic material.

Carcinoma of the Liver.—There were 11 cases, or 3.09 per cent, of primary hepatocellular carcinoma of the liver as an incidental finding in our material. In the same period, however, there were 30 cases of primary malignant hepatoma; 11, or 37 per cent, had an associated cirrhosis. Both types of carcinoma, the massive discrete form and the multicentric form, were encountered. The in-

cidence of primary carcinoma in cirrhosis (3.09 per cent) and that of cirrhosis in primary carcinoma (37 per cent), we feel, corroborates the well-established conception that cirrhosis is the primary condition and that the tumor probably arises from the hyperplastic nodules. Worthy of note at this point is the incidence of primary carcinoma of the liver. Smith[16] in 1933, using part of our autopsy material, found 25 cases in 4,044 autopsies, an incidence of 0.56 per cent. We have collected from our material 30 cases in 12,267 autopsies, an incidence of 0.24 per cent.

Pectoral Alopecia.—Among numerous signs and symptoms connected with cirrhosis of the liver, two findings have received little attention: gynecomastia[17] and loss of axillary hair.[18] At the Cook County Hospital during the past ten years absence of hair on the chest in cases of cirrhosis has been emphasized. There has never been any formal effort made to corroborate this finding.

Of the 244 males in this series the presence or absence of hair on the chest was mentioned in necropsy protocols in 89. Seventy-six of these had no hair and 13 had sufficient hair to prompt such descriptions as "moderate amount of hair," "there is a coarse hairy growth," and "abundant hair on the chest." The interpretation of these statistics is variable. If we assume that the prosector, when doing the autopsy, mentioned the hair on the chest only when he happened to think of it, the incidence of pectoral alopecia is 76 out of 89 cases, or 85.2 per cent. If, on the other hand, the prosector mentioned the hair only when it was absent the incidence is 76 out of 244 cases, or 31 per cent. If the latter is true, it is difficult to explain the 13 cases in which the presence of hair was definitely noted.

SUMMARY

Three hundred and fifty-six fatal cases of cirrhosis of the liver were selected from 12,267 necropsies for study. In 184 cases cirrhosis was the primary anatomic cause of death, while in 172 cases the cirrhosis was an incidental finding. The cases were classified into two main groups: (1) periportal cirrhosis (atrophic or hypertrophic forms), and (2) fatty cirrhosis (hypertrophic form with a large amount of fat and little or no fibrosis). A total of 62.4 per cent of the livers were enlarged and 37.6 per cent were atrophic. Jaundice and hepatorenal decompensation were a frequent finding in the second group of cases (hypertrophic fatty form).

There were 68.5 per cent males and 31.5 per cent females. As to race, 85.9 per cent were white and 14.1 per cent were colored. Jaundice occurred in 169 cases, or 47.7 per cent, and ascites was present in 211 cases, or 59.2 per cent.

As to age, 104, or 29.2 per cent, occurred between 41 and 50, and 111, or 31.2 per cent, between 51 and 60 years. Hemorrhage from esophageal varices was noted in 33, or 9.2 per cent of the cases.

Hypertension was noted clinically in 32 per cent of the cases. However, a higher incidence existed (50.3 per cent) anatomically, considering hypertrophy of the heart as an index of a pre-existent essential hypertension.

Splenomegaly was a constant finding.

The pancreas was fibrosed in 36.2 per cent of the cases and in 5 cases concretions in the pancreatic ducts were found. Cirrhosis was noted in 50 per cent of all cases of pancreolithiasis.

Pectoral alopecia was observed at necropsy in 37 per cent of the males, a finding often of clinical diagnostic aid.

Hepatocellular carcinoma was noted as an incidental finding in 3.09 per cent of the cases, while 37 per cent of the cases of carcinoma of the liver showed cirrhosis.

CLINICAL CHEMISTRY

SEX HORMONE ASSAYS IN THE MENOPAUSE THEIR CLINICAL SIGNIFICANCE*

B. A. Watson, M.D., N. Yolton, and L. Rahls
Battle Creek, Mich.

THE purpose of this communication is to report the results and possible clinical significance of estrogenic and 17-ketosteroid urinary assays of 28 women suffering from the "menopausal syndrome."

SUBJECTS

All patients presented some well-known signs and symptoms of the menopause. For purposes of study they were classified as: 1. Those patients that had either natural or artificial menopause. 2. Those with or without one of the most subjective of all menopause symptoms—"hot flashes."

PROCEDURE

At least two, and in some instances four, complete twenty-four-hour urine specimens were obtained on consecutive or alternate days until consistent daily estrogenic and androgenic values were obtained.

The urines were hydrolyzed and extracted by the Hershberg and Wolfe[1] method and were fractionated by the method of Gallagher and others.[2] Specimens were assayed for estrogenic values by injection in divided doses of an aqueous suspension into 15 ovariectomized mice. Values were reported in terms of gammas of estrone based on a standard dosage-response curve. 17-Ketosteroid assays were done by the Friedgood-Whidden[3] modification of the Zimmerman method, using a Cenco spectrophotelometer and reported as milligrams of androsterone.

Table I

	No. cases	Avg. age (years)	Mean estimate*	Range estimate	Mean androsterone†	Range androsterone
Natural menopause	16	51	6.8	1.1-22.9	9.59	3.7-20.8
Artificial menopause	12	46.8	6.75	2.9-15.0	8.75	4.4-14.25
Menopause with flashes	13	48.5	5.61	1.1-15.0	8.75	4.4-14.25
Menopause without flashes	15	49.6	7.68	1.5-22.9	9.58	3.7-20.8

*Gammas estrone.
†Milligrams androsterone.

DISCUSSION

Table I shows that there is a relationship between the mean values of the female and male sex hormone and symptoms; e.g., patients that did have "hot

*From the Endocrine Research Clinic of the Battle Creek Sanitarium.
Read by title before the Annual Meeting of the Association for the Study of Internal Secretions, May, 1941.
Received for publication, July 6, 1942.

flashes" had lower mean estrogenic values than those that did not exhibit this phenomena. This is not in accord with the observations of Fluhmann and Murphy,[4] who found there was no correlation between symptoms and the estrone content of the blood in the menopause patients.

Other interesting observations during this study were:

1. Some patients with severe menopausal symptoms were found to have female sex hormone values considerably above our normal values in the presence of a normal amount* of male sex hormone (Case 1).

2. Other patients had male sex hormones in the lower limits of normal and female sex hormones at the upper limits of normal.

3. Certain patients had male sex hormones at the upper limits of normal and female sex hormones at the lower limits of normal.

Our observations during this study: the fact that Salmon,[5] and Shorr et al.[6,7] have shown that testosterone propionate in large doses can relieve menopausal symptoms and that all clinicians have observed certain menopausal patients who will not respond to adequate estrogenic therapy, suggests a theory that possibly the menopausal syndrome may be due to:

A. A lack of female sex hormone (Case 2).

B. A lack of male sex hormone (Case 1).

C. Sex hormone imbalance within normal limits, e.g., (1) Low normal male, high normal female (Case 3); or (2) high normal male and low normal female sex hormone (Case 4).

Several other interesting cases which will be reported in detail later were observed. One woman, who five years previously had had a complete hysterectomy and ovariectomy by a competent surgeon, excreted estrone in amounts far above the upper limit of normal. Another patient who had normal amounts of estrone and androsterone was found to have a vaginal smear indicative of marked estrogenic deficiency. She was given adequate estrogenic therapy by her local physician until a normal vaginal smear was attained with no clinical improvement in symptoms.

TREATMENT

The results of the urinary assays were used empirically to guide hormonal treatment. Patients in group A were given female sex hormone. Patients in group B were given male sex hormone. Patients in group C_1 were given male sex hormone and those in group C_2 were given female sex hormone. Some patients with normal female and male sex hormones were given female sex hormone and served as controls (Case 5). Space does not permit publication of all case histories, but the following are examples of types of cases observed:

CASE 1.—Female, aged 40 years. Complaints: Marked nervousness, headache, excitability, fatigue, and loss of libido following an artificial menopause three years previously, with an average excretion of 22.9 gammas of estrone and 8.1 mg. of 17-ketosteroids in twenty-four hours.

Treatment: Testosterone propionate was given in two courses of 10 mg. every four days for six weeks, with a rest period of two weeks in between courses.

---

*On a basis of as yet unpublished observations by Samuels, Yolton, and Winther at the University of Minnesota, arbitrary normal values for female sex hormones were assumed to be from 2.5 to 7.5 gammas of estrone and from 5 to 15 mg. of androsterone per twenty-four-hour specimen at the midmenstrual period. Thus, in those menopausal patients still menstruating specimens were collected at the middle of the cycle.

Results: Decided improvement in stability of equilibrium, loss of headache, definite improvement in fatigue, and a gain of 15 pounds in weight.

CASE 2.—Patient aged 51 years. Complaints: Hot flashes, sinking sensations, excess perspiration, feeling of intense heat, and irregular menses. Average excretion of 2.25 gammas of estrone and 7.59 mg. of 17-ketosteroids in twenty-four hours.

Treatment: Progynon 10,000 units intramuscularly was given three times a week for two weeks, and two times a week for the next two weeks.

Results: Flashes practically disappeared as did most of the subjective symptoms.

CASE 3.—Patient aged 50 years. Complaints: Occasional hot flashes, marked periodic "migraine" headache, beginning shortly after cessation of menses at age 45. Stiffness of hands, back, and knees. Average excretion 6.6 gammas of estrone and 4.4 mg. of 17-ketosteroids in twenty-four hours.

Treatment: Two courses of testosterone proprionate, 25 mg. every five days for six doses, with a two weeks' rest period between courses. After this therapy the patient has been able to maintain good health with 10 mg. every twelve days.

Results: Marked diminution in joint pain and almost complete relief from headaches.

CASE 4.—Patient aged 48 years. Complaints: Artificial menopause of two years' duration, moderate depression, loss of libido, hot flashes, fatigue, and emotional instability. Average excretion 4.35 gammas of estrone and 14.25 mg. of 17-ketosteroids.

Treatment: Ethinyl estradiol (Schering) in doses of 0.15 mg. a day.

Results: Improvement of emotional instability and depression, increased sense of well-being, and reduction of hot flashes from ten to one daily.

CASE 5.—Patient aged 45 years. Complaints: Hot flashes, excessive perspiration, increased nervousness, irritability, and fatigue following hysterectomy and partial ovariectomy three years previously. Average excretion 4.1 gammas of estrone and 5.35 mg. of 17-ketosteroids in twenty-four hours.

Treatment: Patient insisted on hormonal therapy though there was no indication of a deficiency as judged by urinary assay.

Results: No improvement.

Case 1 demonstrates a patient with a comparatively low male, high female sex hormone ratio. *Case 2* is a patient with a deficiency of female sex hormone and adequate male sex hormone. *Case 3* shows a patient with adequate female sex hormone but a male sex hormone which is below normal. *Case 4* is a patient with a high male, low female sex hormone. *Case 5* is an example of one of our control patients with normal male and female sex hormones, adequately treated with female sex hormone with no results.

The results of treatment carried on during the seven months of this study, using urine assays as an empirical guide to therapy, have been gratifying in that treatment has been successful in most instances, and it is felt that the sex hormone assay has pointed the way to successful treatment of some patients and prevented the needless expense of therapy in others who need psychiatric rather than endocrine management.

SUMMARY

Routine determinations of the male and female sex hormones in the urines of menopausal patients may have clinical application in that (a) it may indicate whether male or female sex hormone therapy is needed; (b) aid in explaining a lack of response of certain menopausal patients to the usual estrogenic hormone therapy.

A disproportionate amount of either male or female sex hormones may in some patients cause certain menopausal symptoms which may be alleviated by proper endocrine therapy.

A correlation between the incidence of definite "hot flashes" and the estrogenic and androgenic content of the urine appears to exist.

Estrone has been found in the urines of patients who have had their ovaries and uterus removed.

Correlation of urinary sex hormone assays with clinical results in treatment of the menopause is indicated.

A NOTE ON THE BLOOD GUANIDINE LEVEL IN MIGRAINE SUBJECTS*

HAROLD D. PALMER, M.D., D. B. MC NAIR SCOTT, PH.D., AND
K. A. C. ELLIOTT, PH.D.
PHILADELPHIA, PA.

SINCE migraine headache is held by some authorities to be related to essential epilepsy, it was of interest to determine whether changes in blood guanidine occur in connection with migraine attacks, as Murray and Hoffmann[1] have found to be the case in connection with epileptic seizures. These latter reported that the concentration of guanidine-like substances in the blood of patients with essential epilepsy rose considerably during the aura preceding seizures, reached a high level during the convulsion, and returned to the basic level within an hour thereafter. It was also of interest to check by our technique the basal blood guanidine levels in epileptics and the levels in a group of patients of mixed pathology. A group of normals was tested as a control.

Table I shows the results obtained in this study. Differences between the averages for the groups tested were not significant. Migraine patients showed no

material change in blood guanidine in connection with attacks, and the basal levels in epileptics were normal, as were the levels in the group of mixed pathology.

By comparison of their figures for epileptics with those reported for normal subjects by Andes and Myers[2] (0.21-0.28 mg. per 100 c.c.), Murray and Hoffmann concluded that the basal levels in the epileptics studied by them were higher than normal. Our basal values for epileptics are approximately the same as Murray and Hoffmann's and do not differ materially from our figures for normals. They are higher than the normal level found by Andes and Myers. This discrepancy is possibly caused by the differences in technique used in measuring the color developed in the determination. The photoelectric method used by Murray and Hoffmann and ourselves may give higher values than the ocular method used by Andes and Myers.

The groups studied were composed of about equal numbers of men and women. The persons with migraine, all of whom suffered from typical hemicrania of long standing, were patients of the Migraine Clinic of the Institute of the Pennsylvania Hospital, or were persons connected in some capacity with the Institute. The epileptics were patients resident in the Pennsylvania Hospital, Department for Mental and Nervous Diseases, or in the Philadelphia General Hospital. The normal subjects were obtained from the medical, laboratory, and nursing staffs of the Institute. The group of mixed pathology were from the private practice of one of us.

Blood guanidine derivatives were determined in duplicate by the method of Andes and Myers, except that the color was finally developed in a total of 5 c.c. instead of 2.5 c.c. and was measured by the Klett-Summerson photoelectric colorimeter, using a No. 540 filter.

SUMMARY

1. No sign of abnormality or material change was found in the concentration of guanidine derivatives in the blood of migraine patients previous to or during attacks.

2. The basal level of guanidine-like substances in a number of epileptics was not higher than the level in normal subjects.

THE APPARENT FRUCTOSE CONTENT OF HUMAN EXTRACELLULAR FLUID*

Roger S. Hubbard, Ph.D., and Emerson Holley, M.D.
Buffalo, N. Y.

IN EARLIER publications[1-3] the presence in human spinal fluid of fructose, or of a compound with properties closely resembling those of fructose, has been reported. This substance was found in much greater concentration in spinal fluid than in blood. It has seemed desirable to study human extracellular fluid obtained from sources other than the spinal canal to determine whether this rather unexpected finding is a general or a specific one. In the present note the results of a series of such studies are presented.

The material used in the present study was obtained from medical wards of the Buffalo General Hospital and the Edward J. Meyer Memorial Hospital. A few analyses were made upon specimens obtained at post-mortem examinations made by the department of pathology of the Buffalo General Hospital. Since edema fluid approximates cerebrospinal fluid in its chemical composition, several samples of this material were studied. These were obtained by inserting small metal tubes—the so-called "Southey tubes"—under the skin of patients having gross accumulations of fluid whenever it was possible to do so. It seemed desirable also to study fluids which were rich in protein. Specimens of this nature were obtained either at autopsy or by puncture and aspiration from various portions of the bodies of living patients. The patients for the most part were not fasting when the specimens were drawn. As far as could be determined all the specimens studied were sterile. Blood was taken at the same time as were the specimens of fluid.

The technical methods used were the same as those previously described.[2] Protein and probably other interfering compounds were removed with zinc sulfate and sodium hydroxide in the proportions recommended by Somogyi.[4] When the protein concentration was low, it was possible to prepare suitable filtrates with a minimum dilution of the initial material, but when blood was analyzed, or when the fluids studied were rich in protein, it was necessary to make dilutions which were frequently as great as 1 to 10. The concentrations of zinc and sodium hydroxide used were the same in all instances; only the relative volumes of the sample and of distilled water varied. Final analyses were made, as described in previous articles.[2] Reducing compounds were determined by the method of Folin and Wu,[5, 6] modified, when the concentrations were very

*From the University of Buffalo, Medical School, and the Buffalo General Hospital and Edward J. Meyer Memorial Hospital.

Received for publication, November 5, 1942.

low, according to the recommendations of Hubbard and Allison.[7] Fructose, and fructose-like compounds were determined by the resorcinol technique of Roe.[8] Glucose gives a color when treated with the reagents used by Roe, and it was, therefore, necessary to correct the values obtained for the error produced by the presence in all samples of relatively large amounts of this sugar. Two methods were used for this purpose during the study reported. In some instances the correction was based upon analyses of many solutions of pure glucose carried through Roe's technique. In other experiments an analysis was first made by the technique of Folin and Wu, and a solution was prepared which contained the same concentration of pure glucose as did the specimen of blood or fluid analyzed. This solution of glucose was carried through the procedure simultaneously with the analysis of the unknown solution, and read against a standard solution of pure fructose. By subtracting the value so obtained from the reading given by the sample, the corrected fructose content of the blood or fluid was determined. In a number of instances an attempt was made to determine the effect of a short period of fermentation upon the apparent sugar content of the fluids.[9-11] For this purpose suspensions of washed baker's yeast cells were added to the blood and fluid to give concentrations of 1 c.c. of cells in 5 c.c. of fluid. These stood half an hour to an hour at room temperature, and were then precipitated and analyzed as described above.

Table I contains the results found. Only the corrected values for fructose are given. Because the accuracy of the fructose determinations in fluid were much greater when the filtrate analyzed was only slightly diluted, the degree of dilution is given in each instance. The determinations of "fructose" content after fermentation are included, but the nonglucose reducing compounds, which appeared to add little to the value of the data, have been omitted. The average values of these substances were equivalent to 6 and 8 mg. of glucose per 100 c.c. of fluid and blood, respectively. In only one instance did a study appear unsatisfactory. Difficulty was experienced in removing protein from the abdominal fluid in Experiment 27, and it was necessary to reprecipitate with a second addition of zinc and sodium hydroxide in this instance. Whether this procedure affected the significance of the results could not be determined.

We believe that a number of interesting facts are shown by Table I. The average concentrations of glucose in the blood and fluid specimens were approximately the same—99.0 mg. per 100 c.c. in the former, and 103.7 mg. in the latter material. In a majority of the specimens, however, the concentration was higher in the extracellular fluid than in the blood. This difference was not due to the presence of nonfermentable reducing compounds in the specimens of fluid analyzed. It probably resulted from a number of causes. These include the relatively greater water content of the fluids, and the relatively low glycolysis which results from the low concentrations of cells which most of them contained. (Note that in the specimens of synovial fluid rich in cells the glucose content was unusually low.) It is possible also that an uneven distribution of sugar between the blood and the fluid, similar to that which has been reported in spinal fluid,[12] may have influenced the results, for most of the fluids were not taken in a postabsorptive state, and the findings may represent an equilibrium attained when the blood sugar concentration was high shortly after a meal.

Under glucose are given the concentrations of total reducing compounds expressed as glucose.
Under fructose are given the concentrations of substances reacting with resorcinol expressed as fructose.
The filtrates prepared from blood represented a 1:10 dilution of the initial material.
Fructose values have been corrected for the reaction given by the glucose present. The correction used for the starred (*) values were based upon determinations run simultaneously with the analyses; for others a standard correction was determined in preliminary experiments.

Sugar may have been removed from the blood by active metabolic processes, and a complete re-establishment of conditions of equilibrium by diffusion not have been reached. It is interesting to note that in a series of analyses of blood and spinal fluid made by identical methods, glucose was regularly present in the spinal fluid in lower concentrations than in the blood.

The results of the fructose determinations were also interesting. The average value of the corrected "fructose" concentrations in all the 33 fluid specimens studied was 0.7 mg. per 100 c.c. This differs markedly from the results upon spinal fluid specimens previously reported, for the average found upon 32 specimens reported previously was 2.9 mg. per 100 c.c. The contrast between the individual specimens was as marked as was the difference between these averages. In only 8 fluid specimens was the concentration greater than 1 mg. per 100 c.c., while only four spinal fluid specimens contained concentrations which were less than this. Each of these four specimens was obtained from a patient with meningitis, and there seemed to be good reasons for associating the low values with the clinical condition of the patients.[3] In 26 of the 32 spinal fluid specimens the concentration of fructose was greater than 2 mg. per 100 c.c., while there were only two results in the present study which contained such amounts of fructose. It seems obvious, therefore, that there is a marked difference between the apparent fructose content of cerebrospinal fluid and other types of extracellular fluid.

The data were examined to determine whether there were any differences between values upon fluids obtained from different body cavities. As far as could be determined there were no such differences. The highest fructose concentration found was in a specimen of edema fluid, but another specimen apparently contained none of the sugar, and in several others the concentrations were of the order of 0.1 or 0.2 mg. per 100 c.c. As a comparison with peripheral edema fluid, which is almost regularly very low in protein, a number of specimens of pericardial fluid, in which the content is regularly high, were analyzed. The results of these analyses also covered a wide range, from 1.5 to 0.0 mg. per 100 c.c. The rather limited number of other types of fluid, chest fluid, abdominal fluid, and synovial fluid, all showed similar variations.

It seemed possible that the method of handling the specimens might have affected the results. As already stated, when the protein content was high, it was necessary to dilute the material in order to obtain a filtrate suitable for analysis; when the protein concentration was low, marked dilution was unnecessary. The average of the values obtained when specimens were diluted five or ten times was 0.65, and when diluted less than five times it was 0.76 mg. per 100 c.c. Such variations in technique, therefore, had no significant effect upon the results. It is certain, however, that the probable significance of any single figure obtained when the more concentrated filtrates were analyzed was greater than when dilution was necessary.

A comparison between the fructose content of blood and of the various fluids was made. In the 23 studies in which results of both determinations were available the average fructose content of blood was 1.1, and of the fluids, 0.8 mg. per 100 c.c. This relationship is quite different from that observed in the study of

spinal fluid, for in that investigation the average fluid content of fructose was approximately six times as great as was the concentration in blood. If the figures presented in Table I are examined in detail, it is evident that results upon individual subjects agree at least as closely together as do the average ones, for in only a third of the studies do the results differ by 0.5 mg. per 100 c.c. or more. In all but one of the analyses in which the differences were of this magnitude, both the blood and the fluid were diluted 1:10, and the errors of both determinations were great.

Because there was so little difference between the average blood and fluid values, it seemed worth while to calculate the correlation coefficient between the two sets of figures. This had been done in the study of spinal fluid, and no significant correlation was found. In this instance the coefficient was +0.64 ± 0.08. These figures make it seem probable that the fructose, or fructose-like compound, found in the extracellular fluids is derived from the blood, or at least is in equilibrium with some similar materials in the blood.

In the discussion of the results obtained in the previous study[2] it was pointed out that it was possible that no fructose is present in blood, because the accuracy of the determinations is so low. It seems to us that the correlation which appears to exist between the fructose in blood and extracellular fluid is evidence of the actual existence of some similar compound in both media.

An attempt was made to determine whether the material giving the color with resorcinol was actually fructose. In 14 experiments the fluid was inoculated with massive suspensions of yeast cells, allowed to incubate, and the apparent fructose content was determined. The results could not be considered satisfactory. In all but 4 of these specimens there was some apparent destruction of "fructose," and in some instances the destruction was marked. There was frequently noted, however, a measurable color when the incubated material reacted with the resorcinol reagents. The results with blood were essentially similar. There are at least three possible explanations for this finding. It is possible that at least two different substances in blood and extracellular fluid react with the resorcinol reagent, and that only one of these is readily destroyed by such suspensions of baker's yeast as were used in these experiments. The second possibility is that some fructose may have escaped destruction by the yeast suspensions used. It was found that some yeast suspensions do not ferment fructose readily, and it is possible that such small amounts of fructose as were apparently present in these solutions may have escaped destruction. The third possible explanation of the results is an extraction from yeast cells of some compound which will react with the resorcinol reagent. A suspension of yeast cells in distilled water has been incubated and analyzed as a part of each study presented in the table. These control suspensions regularly showed no color upon analysis. It was found, however, that certain alkaline solutions do extract from yeast cells measurable amounts of some compound which gives the resorcinol reaction, and it does not seem impossible that the blood and fluids may have had a similar action upon the yeast cells. It is, therefore, impossible to decide the exact nature of the compound which gave the resorcinol reaction in the unfermented blood and fluid specimens. It may all have been fructose; it may have

been some compound which resembles fructose, but which is slowly fermented by or adsorbed upon yeast cells: there may have been two compounds present which react with the resorcinol reagent, only one of which is acted upon by suspensions of washed cells of baker's yeast.

CONCLUSION

Results of the determination of the apparent fructose content of abnormal human extracellular fluid obtained from various body cavities have been carried out. Traces of some compound giving a reaction with the resorcinol reagent were present in two-thirds of the specimens. The amounts were much smaller than those previously found in cerebrospinal fluid. They appeared to be derived from, or to be in approximate equilibrium with, similar substances in blood. Fermentation with resting yeast cells was carried out in an attempt to identify the compound definitely as fructose, but the identification was not made with certainty.

LABORATORY METHODS

GENERAL

A STERILITY TEST FOR SULFANILAMIDE POWDERS*

Maurice Landy, Ph.D., and Elizabeth J. Oswald, B.S.
Washington, D. C.

THE report of a death from tetanus traced to a contaminated sulfonamide powder[1] makes it evident that there is a present need for an adequate test to determine the sterility of these valuable chemotherapeutic agents. There would appear to be no question regarding the necessity of subjecting the powders to heat sterilization,[2, 3, 4] but there seems to be some controversy as to the amount of heat which can be applied without altering the drugs to such an extent as to render them useless and, in some cases, actually dangerous to administer.[5, 6] The margin of safety between the amount of heat necessary to kill any organisms present, and the amount which will yield a product unfit for use is comparatively small. It is therefore important to have available a test for the determination of the sterility of sulfonamide powders.

The procedure which has been used successfully in this laboratory is as follows: The contents of a shaker package (5 grams of sulfanilamide) are transferred aseptically to a flask containing 500 c.c. of sterile water. The flask is vigorously shaken for five minutes, allowed to stand for thirty minutes at room temperature, and shaken again for five minutes. The undissolved sulfanilamide is allowed to settle and 5 c.c. of the supernatant fluid are added to each of two tubes containing 20 c.c. of Brewer's medium.[7] The tubes are incubated at 37° C. for a period of seven days and examined for evidence of growth.

In the development of the above procedure it was necessary to select a medium capable of supporting both aerobic and anaerobic growth, and which would, in addition, nullify the bacteriostatic effect exerted by the sulfonamide under test.

Initial experiments demonstrated that Brewer's medium fulfilled these requirements. It contains a sufficient amount of sulfonamide-inhibitor to permit growth of three selected test organisms (*Staphylococcus aureus*–Pure Food and Drug strain, and Army Medical School strains of *Escherichia coli* and *Clostridium tetani*) in the presence of 50 mg. of sufanilamide. This amount of sulfanilamide is the maximum amount which could be present per tube of Brewer's medium in the execution of the aforegoing sterility test. Inasmuch as Brewer's medium, by assay,[8] contains 2 micrograms of p-aminobenzoic acid per 20 c.c., with the possible presence of additional sulfonamide-inhibitors, it

seems to be adequate to neutralize the bacteriostatic action of the sulfanilamide under our test conditions. It was found that the addition of an excess of sulfonamide-inhibitor (50 micrograms p-aminobenzoic acid) offered no apparent advantage in the initiation of growth by a smaller number of organisms, although there was some evidence to show that the aerobic organisms grow out more rapidly in the presence of an excess of p-aminobenzoic acid. The test organisms, inoculated into tubes of sulfonamide-containing Brewer's medium in numbers ranging from 3 to 100,000 grew out well in 48 hours. The assembled data on recovery of test contaminants added to Brewer's medium containing sulfanilamide is given in Table I.

TABLE I

RECOVERY OF TEST CONTAMINANTS IN BREWER'S MEDIUM* IN THE PRESENCE OF SULFANILAMIDE

TEST ORGANISM	INOCULUM NO. CELLS	SULFANILAMIDE 50 MG./TUBE		SULFANILAMIDE 50 MG. + P-AMINOBENZOIC ACID 50 γ/TUBE		CONTROL NO SULFANILAMIDE

*20 c.c. volumes in 25 x 200 mm. tubes. ++ = heavy growth; + = moderate growth; – = no growth.

In order to determine the efficiency of the method in the recovery of a spore-bearing pathogen from sulfanilamide powder, samples were artificially contaminated with small numbers of *Cl. tetani*. Two packages of sterile sulfanilamide powder were contaminated with 20,000 and 450 cells of *Cl. tetani*, respectively. The powders were returned to their packages, sealed and allowed to remain at room temperature for two days. Contaminated and sterile sulfanilamide powders were then examined by the test procedure. No growth was observed in the sterile sulfanilamide controls, while tubes containing contaminated sulfanilamide powder showed excellent growth of *Cl. tetani* within 48 hours. It was further noted that when the flasks containing the suspension of the artificially contaminated sulfanilamide powders were allowed to stand at room temperature for 48 hours, recovery of the organisms was effected even though the sulfonamide powder was completely dissolved and the spores of *Cl. tetani* were necessarily exposed to a 1000 mg. per cent solution of the drug for at least a portion of that length of time. This is further evidence of the extreme resistance of *Cl. tetani* spores to high concentrations of sulfanilamide.

This procedure is applicable to other sulfonamides as well. It is necessary, however, first to determine the maximum quantity of drug which is inactivated by the sulfonamide-inhibitors present in Brewer's medium.

SUMMARY

A test for the determination of sterility in sulfanilamide powder is presented. It is simple in operation, and effective in the recovery of small numbers of spore-bearing pathogens from artificially contaminated sulfanilamide samples.

A DEVICE FOR INJECTIONS INTO THE EAR OF RABBITS*

WALTER KOCH, JERUSALEM, PALESTINE

WHEN a rabbit has to be injected again and again, difficulties arise as the principal veins become obliterated.

This difficulty can be overcome by a simple instrument. To the box (*a*) of an ordinary pocket lamp with an elevated convex lens (*b*) is attached a strong metal wire (*c*) of 4 mm. diameter, bent to correspond to the shape of the

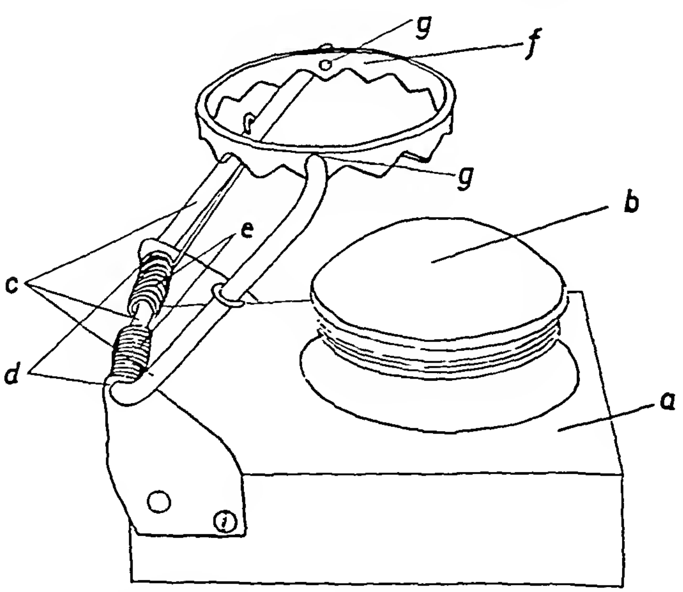

Fig. 1.—*a*, Battery casing; *b*, convex lens; *c*, metal wire; *d*, bearings; *e*, spring coils; *f*, serrated ring; and *g*, small holes in *f* into which the ends of *c* are inserted.

*From the Department of Hygiene, The Hebrew University, Jerusalem.
Received for publication, December 17, 1941.

lamp which runs in two bearings (*d*). The lower end of the wire is passed through two stiff spring coils (*e*) to give it the necessary pressure. At the upper end of the wire there is attached a serrated ring (*f*) which fits right over the convex lens of the lamp.

When using the instrument, the wire and the ring are lifted from the lens (as shown in the drawing), and the ear is interposed between lens and ring. The pressure of the springs fixes the ear with the teeth of the ring. Since the ring is serrated, the blood vessels of the ear under the teeth are compressed while there is free circulation in the vessels under the free spaces between the teeth.

The advantage of the convex lens is that it raises the ear of the rabbit above the ring so that the syringe can easily be directed to the vein to be injected without interference.

AN IMPROVED METHOD FOR DETERMINING THE SEDIMENTATION RATE OF THE RED BLOOD CORPUSCLES*

F. Rappaport, Ph.D., Palestine

According to Reichel, the sedimentation rate is independent of the height of the blood column if the depth of the sedimentation does not exceed one-third the entire blood column. Also, it is independent of the volume of the test tube if the diameter of the latter is not smaller than 1.4 mm. With a narrower tube the capillary action would interfere perceptibly with the determination. The sedimentation rate also depends on the external temperature, being accelerated by heat and retarded by cold. In order to exclude this source of error—which in tropical countries shows its effect especially in summer, while in temperate zones it is more conspicuous in the winter—the following apparatus was constructed:

Apparatus.—This consists of a wide-necked thermos flask (see Fig. 1) fitted with an inner rack to hold the sedimentation pipettes. The stand is built to hold six sedimentation pipettes, springs keeping it at a given height. At the bottom of the stand six small test tubes with side apertures (2 to 3 mm. above their lower end), are fixed by means of small springs. The sedimentation pipettes are placed into these test tubes when a determination is being carried out.

Glass tubes (see Fig. 2) with a diameter of 1.45 to 1.6 mm., approximately 21 cm. long, the lower part without graduation, and cut flat. The ungraduated part corresponds to one-fourth the graduated part, i.e., from 30 to 40 mm. The upper graduated section is divided into centimeters, showing millimeter graduation as well. Length of graduated part is from 120 mm. to 160

*From the Beilinson Hospital, Petach Tiqua, Palestine.

Received for publication, May 18, 1942.

mm. Over the top a soft and transparent tubing of Para rubber is fitted, containing a movable glass bead.

Reagents.—1. 3.8 per cent neutral sodium citrate solution (tribasic). 2. Glycerol to moisten the tubing.

Procedure.—The pipettes should be rinsed with distilled water and dried with warm air only (no acetone or alcohol). Before blood is drawn from the finger tip the entire pipette should be rinsed with citrate solution. Then the citrate should be sucked up to the ungraduated part. This citrate is blown out into a small test tube. The blood is then allowed to flow (by capillary action) into the pipette—which should lie in as horizontal a position as possible—up to mark 0. Then let the blood flow into the citrate test tube, mix it well, but avoid formation of bubbles. The sedimentation test may be set up

Fig. 1.

Fig. 2.

immediately or, at the latest, in the course of the next five hours. If the sedimentation is set up immediately, the pipette may be used again without being cleaned beforehand, otherwise it may be used only after thorough cleaning, drying, and renewed moistening with the citrate solution.

For setting up the reaction, moisten the tubing with a small drop of glycerol at its lower end. Slip almost the entire length of the rubber tubing (which is about 4 cm.) over the pipette. The glass bead pressed aside, the blood citrate mixture should be sucked up to mark 1. By drawing the rubber tubing upward, the blood column is raised up to mark 0. (If necessary

correct by shifting the bead inside the tubing.) Now the pipette is inserted into the stand which is put into the thermos flask, previously filled with water at 20° C. Readings are taken after thirty, sixty, and one hundred and twenty minutes with a slow sedimentation and after thirty and sixty minutes only if the sedimentation is fast.

A SODIUM LAURYL SULFATE SOLUBILITY TEST FOR THE IDENTIFICATION OF PNEUMOCOCCI*

MILWARD BAYLISS, PH.D., M.D., CHICAGO, ILL.

SINCE Neufeld in 1900 demonstrated that pneumococci were soluble in bile, it has been customary to differentiate this group of bacteria from streptococci by treating the organisms with bile or one of the bile salt preparations. The difficulty in obtaining a clear specimen of bile is an obvious disadvantage when it is to be used for a test in which the final criterion is the clearing of a suspension of the organisms. Within recent years sodium desoxycholate has to a considerable extent replaced the use of bile. This bile salt gives a clear colorless solution, but it has the disadvantages of being expensive and, if the pH of the media is 6.6 or less, desoxycholic acid will precipitate and give a cloudy solution which obscures the test.

Lysis or clearing is considered by some investigators to be hastened by any process that kills the pneumococcus without impairing its enzyme activity (Mair, 1929). Bile, sodium desoxycholate, sodium ricinoleate, and most of the other substances which accomplish this are surface tension depressants. Because sodium lauryl sulfate possessed this property of lowering surface tension, it was thought that it might parallel bile in its action on pneumococci and streptococci. This compound was soluble in the presence of calcium and magnesium ions and in the presence of acid or alkali. With its low cost and the ease of obtaining a clear colorless solution, it would be more satisfactory than bile or sodium desoxycholate if the same results were obtained.

Bayliss (1937) studied the visible action of sodium lauryl sulfate on various microorganisms. Gram-negative organisms were usually cleared while gram-positive organisms remained turbid when broth cultures were treated with solutions of this compound. The pneumococcus was a notable exception to this rule. All available strains of pneumococci tested were found to be cleared in thirty minutes at 37° C. when the concentration of sodium lauryl sulfate was 0.2 per cent. All streptococci tested were found to be unaffected. The ease of obtaining

*From the Department of Bacteriology and Public Health, College of Medicine, University of Illinois, Chicago.
Received for publication, May 25, 1942.

satisfactory material for carrying out this test and of reading the results, because of the water clearness of the solution of sodium lauryl sulfate, made this procedure appear to be a desirable substitute for the bile solubility test. The cultures available at that time were limited. Since then the author has continued his observations on several hundred strains of pneumococci and streptococci.

EXPERIMENTAL

The action of sodium lauryl sulfate was studied by adding 0.5 c.c. of various concentrations of crude sodium lauryl sulfate* to an equal amount of a twenty-four-hour serum infusion broth culture of the organism. Controls of the culture plus saline, as well as uninoculated media plus sodium lauryl sulfate solution were made for comparison. After thorough shaking, the tubes were examined at frequent intervals and the degree of clearing was noted.

During the past five years several hundred pneumococcus cultures, including all the 32 types for which commercial typing antisera are available, have been subjected to the action of sodium lauryl sulfate. A few strains of pneumococci which did not fall in the types for which commercial typing antisera are available have also been tested. All freshly isolated strains have been readily soluble. Occasionally an old laboratory strain was encountered which was soluble with difficulty or, in rare instances, was unaffected. In such instances the effect on the organism of sodium desoxycholate or of bile was also proportionately decreased. Treatment of the pneumococcus in a manner which prevented the lytic action of bile also stopped any effect by sodium lauryl sulfate. Cultures heated to boiling for ten minutes were unaffected by either substance.

Pneumococci which have been recently isolated showed rapid clearing even in dilutions of sodium lauryl sulfate as high as 1:2,560. Table I illustrates the comparative clearing action of this compound and of sodium desoxycholate on type XI pneumococcus.

Numerous strains of pneumococci have given results comparable to those in Table I. With these results in mind a routine test for use in the identification of pneumococci was established. This consisted of adding 0.1 c.c. of a 2 per cent solution of sodium lauryl sulfate to 0.9 c.c. of a twenty-four-hour infusion broth culture. A control in which 0.1 c.c. of normal saline was added to 0.9 c.c. of the culture was also performed, although the results were striking enough so that this was not usually necessary. Both tubes were then incubated at 37° C. for thirty minutes before a final reading was made. With this routine procedure all freshly isolated strains of pneumococci were cleared.

A 2 per cent solution was best prepared by making 2 Gm. of crude sodium lauryl sulfate up to 100 c.c. with water. It was found desirable to heat, but

*"Dreft" is a sodium lauryl sulfate product manufactured by Procter and Gamble Company. It consists of about 50 per cent inorganic material, mainly sodium sulfate, and about 50 per cent organic compounds. Of the latter, about half is sodium lauryl sulfate and the remainder are compounds very similar in structure and properties, such as sodium sulfate esters of decyl, myristyl, cetyl, and oleyl alcohols. The normal variation of composition of the organic substances corresponds to that of coconut oil and palm kernel oil from natural sources.

"Dreft" is very soluble in water but frequently on standing at room temperature a white precipitate will settle out of the solution. This can easily be redissolved by warming. If kept at 37° C., the solution remains clear indefinitely.

McClure and Harris (1940) have recommended the use of a similar sodium lauryl sulfate product, Duponol WA, in solubility tests for pneumococci.

TABLE I

COMPARISON OF THE CLEARING ACTION OF SODIUM LAURYL SULFATE AND SODIUM DESOXYCHOLATE ON DIPLOCOCCUS PNEUMONIAE (TYPE XI)

CONCENTRATION	SODIUM LAURYL SULFATE					SODIUM DESOXYCHOLATE				
	TIME (MINUTES)					TIME (MINUTES)

2, 25-50 per cent clearing.
1, 10-25 per cent clearing.
-, less than 10 per cent clearing.

not to autoclave, to aid in dissolving the compound. To remove any particles of dirt it was passed through filter paper. When kept at 37° C., it remained ready for use at any time.

Numerous strains of streptococci, including alpha, beta, and gamma types have been unaffected by the sodium lauryl sulfate solution. In each instance there has been either no clearing action or occasionally a slightly increased turbidity, possibly due to the increased dispersion of the intact organisms by this surface tension depressant. Parallel tests with bile and sodium desoxycholate have in each instance given similar results.

Microscopic examination at frequent intervals of the pneumococcus cultures following the addition of the sodium lauryl sulfate demonstrated decreasing numbers of intact organisms. With streptococci no disappearance of the bacteria was noted. Cultures of gram-negative bacteria to which relatively high concentrations (1:50 to 1:100) of the compound have been added usually showed macroscopic clearing, with a marked increase in the viscosity of the media, though microscopic examination revealed no marked lytic action on gram-negative organisms, such as *Escherichia coli*.

SUMMARY

Sodium lauryl sulfate rapidly cleared suspensions of pneumococci with disintegration of the organisms. Several hundred strains of pneumococci of various types have been studied and found to be lysed rapidly in a 0.2 per cent concentration of the compound.

All freshly isolated strains showed definite clearing within thirty minutes. Streptococci under the same conditions were unaffected.

The test is best performed by adding 0.1 c.c. of a 2 per cent solution of crude sodium lauryl sulfate ("Dreft") to 0.9 c.c. of a 24-hour culture. Usually

the results can be determined in a few minutes, but if clearing does not occur, it is necessary to incubate the mixture at 37° C. for one-half hour before the final reading.

A METHOD FOR MAKING SECTIONS OF BONES AND TEETH*

Elbert B. Ruth, A.M., Ph.D., Cincinnati, Ohio

THE usual methods of studying the finer aspects of bone and tooth structure employ thin celloidin or paraffin sections, or slabs of bones or teeth sawed from the specimen and ground as thin as possible by some appropriate technique. The former method yields satisfactory studies of the cytologic picture, and the latter is capable of producing excellent studies of Haversian systems with their lamellae, lacunae, and canaliculi. Both of these methods are valuable and necessary, but both have certain drawbacks.

The method herein described, in supplementing the other methods, gives excellent pictures of bone architecture, with only the canaliculi showing poorly. The lamellae and lacunae, however, are demonstrated in a striking manner not seen in ground sections, or in the celloidin or paraffin sections. An additional advantage is obtained through the use of unstained and relatively thick (80μ to 120μ) sections, which offer a three-dimensional picture.

PROCEDURE

This method may be applied to bone in any state—fresh, fixed, or ordinary dried skeletal material. The best results are obtained when the bone is free from soft tissues and grease. Fresh bone may be fixed first or macerated in warm water until clean. Any appropriate fat solvent may be used for degreasing; acetone works well with fresh bone, and either acetone, benzene, or gasoline is satisfactory for dry bones.

Decalcification is accomplished in 5 per cent hydrochloric acid. The use of nitric acid is not recommended, since it seems to make the organic matrix brittle in some cases, and this results in a certain amount of splitting of the tissue. Hydrochloric acid decalcifies rapidly and does not cause maceration of the organic matrix if the tissue is not left in the reagent too long. Decalcification is considered to be complete when about 10 c.c. of the acid solu-

*From the Department of Anatomy, College of Medicine, the University of Cincinnati.
Received for publication, May 25, 1942.

tion covering the specimen is added to an equal volume of equal parts of 5 per cent ammonium hydroxide and 5 per cent ammonium oxalate, and no precipitate is formed. When decalcification is complete, the tissue is washed in tap water until the acid is removed.

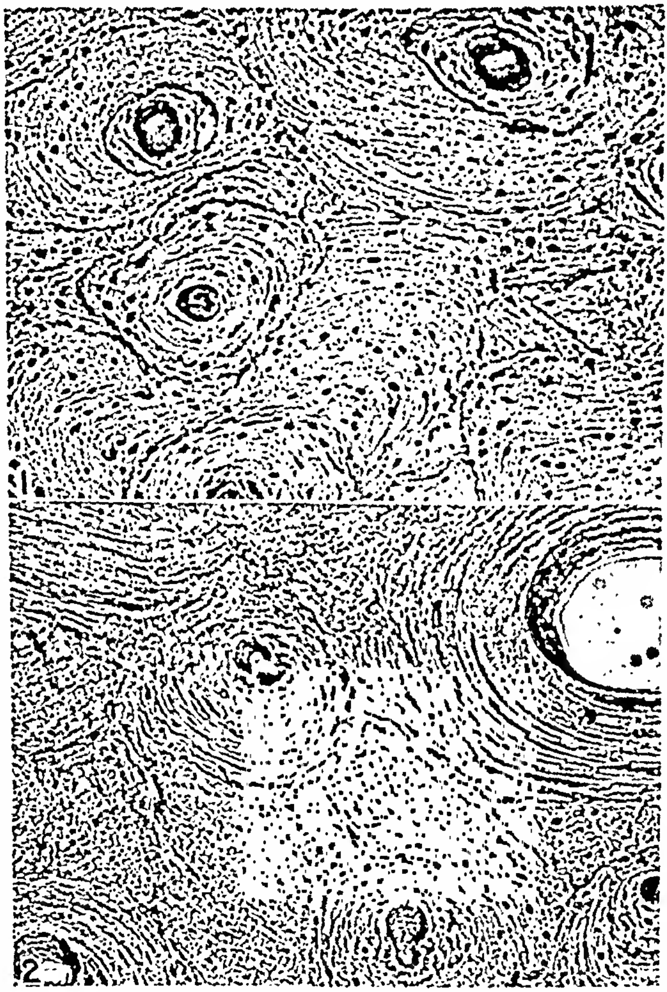

Fig. 1.—Section of a human metacarpal bone viewed with the substage condenser lowered and the concave mirror tilted to bring out the lamellar structure. The black dots are the lacunae (×160).

Fig. 2.—Another field of the same section as Fig. 1, showing the third dimensional effect obtained when focusing on a greatly enlarged Haversian canal. This section was cut freehand with a razor blade (×160).

The tissue next is placed in a potassium hydroxide-glycerin solution, such as is used in the Schultz technique for clearing embryos for demonstration of the skeleton. The formula used is:

Water	77 c.c.
Glycerin	20 c.c.
Potassium hydroxide	3 Gm.

The tissue remains in this solution until the matrix becomes semitransparent, when it is placed in rising grades of glycerin (50 per cent, 75 per cent, and 100 per cent) until completely cleared.

The glycerin is removed from the tissue by washing in several changes of 70 per cent alcohol. This is followed by replacing the 70 per cent ethyl alcohol with n-butyl alcohol, C.P. Two or three baths of butyl alcohol may be required in order that there may be no ethyl alcohol left in the tissue. The last butyl alcohol bath may be saved, and the alcohol may be used later to dissolve the paraffin out of the cut sections.

The next step is to infiltrate the specimen with paraffin and to embed for sectioning. At least three paraffin baths (one hour or longer in each bath—according to the size of the specimen) are recommended.

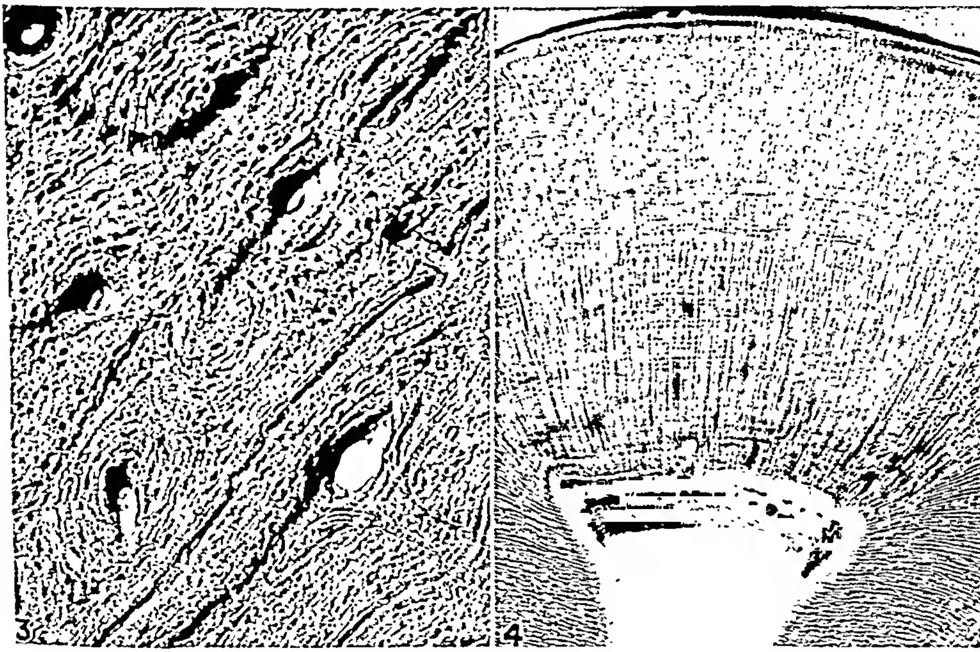

Fig. 3.—Section of the femur of a child about 8 years old. The substage condenser has been elevated as high as possible, and the concave mirror is tilted to give the impression of viewing the section by reflected light. Vascular channels are shown well, and the third dimensional effect is demonstrated. The black dots are lacunae. Section cut on microtome—120μ ($\times 160$).

Fig. 4.—Section of the tooth of a fish to illustrate the application of this method to the sectioning of teeth. Freehand section cut with a razor blade ($\times 160$).

Sections may be cut in any of three ways: (1) freehand with a razor blade; (2) with a well microtome and a straight-edge razor, or a microtome knife; or (3) with a celloidin microtome that will cut sections up to 200μ. The sections in Figs. 1, 2, and 4 were cut freehand. The section in Fig. 3 was cut at 120μ on a celloidin microtome. By cutting sections of different thicknesses, from 40μ to 200μ it appears that the sections from 80μ to 120μ give the best pictures of the arrangement of the circumferential lamellae, Haversian systems, interstitial lamellae, and the interrelationships of the Haversian canals.

Sections are put into a container with enough butyl alcohol to cover them. They remain rolled up until the butyl alcohol has dissolved away the paraffin in which they are embedded. Removal of the paraffin is accomplished

in the paraffin oven. The first butyl alcohol bath will remove most of the paraffin, but two more baths in butyl alcohol are necessary to remove all traces of paraffin. Glycerin is added to the butyl alcohol of the final bath in rising percentages—25 per cent, 50 per cent, and finally 100 per cent. Glycerin replaces the butyl alcohol and clears the sections.

The sections are mounted more or less permanently in glycerin jelly. They may be studied in glycerin, but need to be in a semisolid medium for photomicrography, or for handling over a period of time. Greater permanence may be given the slides by ringing the cover slip with gold size and Bell's cement. A thick jelly is recommended, according to the following formula:

U.S.P. granular gelatin	15 Gm.
Distilled water	50 c.c.
Glycerin	55 c.c.
Phenol crystals	2 Gm.

The gelatin is put into the water and melted with gentle heat. The glycerin may be added at this time after first dissolving the phenol in the glycerin. The melted glycerin jelly should be filtered through moist, hot flannel before using.

The sections are taken from pure glycerin and pressed between two filter papers to remove excess glycerin. The melted jelly is pipetted onto a warmed slide (the number of drops necessary is easily ascertained after several trials), and the section is placed in the jelly. The coverslip is applied, after warming over a flame, and the excess gelatin is pressed out from under the cover slip. Slides are readily cleaned after the gelatin hardens by cutting away any gelatin extending onto the slide beyond the cover slip. Wiping the slide with a damp cloth completes the cleaning process.

Proper use of the microscope in the study of the prepared slides is quite as important as the different steps of preparation of the tissue. The lighting effects that are desired to bring out the details of the sections, are obtained by manipulation of the substage condenser and mirror. In one position the section appears to be illuminated by reflected light, as seen in Fig. 3. Another position of the mirror and condenser gives the appearance of lighting by transmitted light, as in Figs. 1, 2, and 4. In the former position the surface topography of the section is seen in three dimensions, and by proper focus the details of the vascular channels and lacunae are emphasized. These details may be studied with various magnifications. In the latter position the details of lacunae and lamellae are emphasized. This brings out the true architecture of the bone—the boundaries of the Haversian systems and the relations of the interstitial and circumferential lamellae being displayed in a striking manner. To produce the effect of reflected light the condenser is raised as high as possible, and the mirror is tipped in different directions until the desired result is obtained. To bring out the lamellar structure the condenser is slowly lowered, and again the mirror is moved in different directions until the desired effect is obtained. The concave mirror is always used.

The use of the higher grades of ethyl alcohol for dehydration, and xylol, or other clearing reagents ordinarily used before passing the tissue into

paraffin, hardens the ostein, and changes it optically so that the structural details are shown very poorly, or not at all.

The use of Lendrum's technique (Carleton, 1938) for softening dense fibrous tissue was found to be advantageous with teeth and with bones larger than rat bones. The decalcified bone is placed in a solution of 4 per cent phenol for four to six days at room temperature. If any signs of maceration appear, the treatment must be stopped at once. The bone is washed in several changes of water at 45° C. until the odor of phenol no longer can be detected. The specimen is then cleared as described. The rest of the treatment is unchanged.

SUMMARY

Fresh, fixed, or dried bone specimens are decalcified in 5 per cent hydrochloric acid.

The decalcified bone is cleared in potassium hydroxide-glycerin solution, and finally in rising grades of glycerin (50 per cent, 75 per cent, and 100 per cent).

Glycerin is removed from the tissue by washing in 70 per cent alcohol, which is replaced by n-butyl alcohol (three baths).

The specimen is infiltrated with paraffin* and is embedded in a block of suitable size. Sections may be cut freehand with a razor blade; on a well microtome, with a section razor or microtome knife; or on a celloidin microtome. Thick sections are used for study, 80μ to 100μ.

Paraffin is dissolved out of the sections in several changes of n-butyl alcohol, and the sections are placed in several changes of rising grades of glycerin: 25 per cent, 50 per cent, and 100 per cent.

From 100 per cent glycerin the sections are mounted in a thick glycerin jelly, and are studied microscopically with different lighting effects attained by the raising and lowering of the substage condenser, and the movement of the concave mirror to reflect the light from different angles.

EYEGLASSES TO BE USED WITH THE BINOCULAR MICROSCOPE*

Alfred Plaut, M.D., New York, N. Y.

FOR several years a pair of special eyeglasses has proved helpful to me, a hyperopic person, while using the binocular microscope. The glasses are crescent-shaped, 1.3 cm. high in the center. Over the upper concave border, I look into the oculars of the microscope. With the bitukni binocular one can sit in a very convenient position without strain on the muscles of the neck. (These eyepieces form an angle of 135° with the vertical tube.) I had about one-third of the upper rim of the oculars removed on the lathe, flush with the tube of the eyepiece, enabling me to get as near the eyepieces as can be done without glasses, and thus getting the benefit of the whole microscopic field. It also prevents the eyeglasses from catching at the microscope and it permits free movement of the head. When the upper portion of the eyepieces is cone-shaped, as in the Spencer outfit, this is unnecessary.

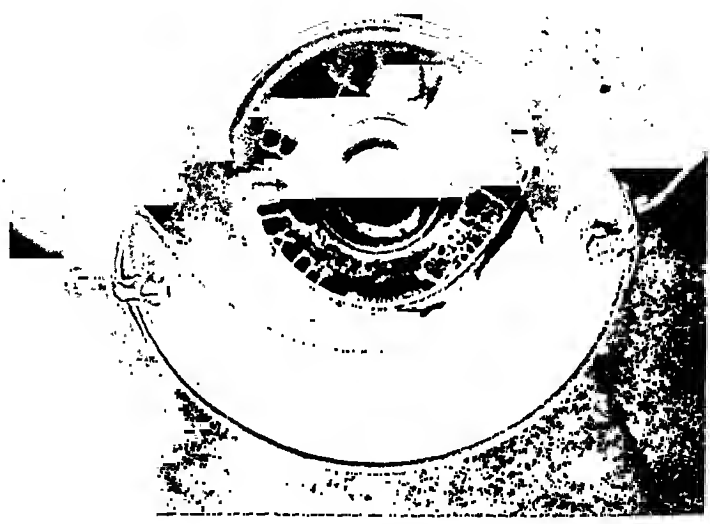

Fig. 1.

The glasses are weaker than the ones used for reading. Hence, without eye-strain and without much moving of the head, it becomes possible to overlook the table I am working on. At the same time, the glasses are strong enough for writing and reading. The strength of the glasses is a matter of individual choice. Except for continued reading and for observation of finer details, such glasses can be used for most laboratory activities. This obviates the too frequent changing of eyeglasses. Fig. 1 is self-explanatory.

THE PITUITRIN CONCENTRATION TEST OF RENAL FUNCTION*

NORMAN G. SCHNEEBERG, M.D., WILLIAM B. LIKOFF, M.D., AND
I. EDWARD RUBIN, M.D., PHILADELPHIA, PA.

POSTERIOR pituitary extract inhibits water diuresis by producing an increased reabsorption of water by the renal tubular epithelium. Its use, therefore, has been advocated as a substitute for the required period of water deprivation necessary in the performance of the standard Fishberg test. This period of water restriction represents a considerable inconvenience to the patient and a source of error when the patient fails to cooperate.

The use of pituitary preparations in the performance of kidney function tests was first advocated in 1930,[1] and since then sporadic references to its use have appeared in the literature.[2] Recently, Sodeman and Engelhardt[3] attested to the efficacy of surgical pituitrin in producing a urine, in 15 normal subjects, as concentrated as that produced by a "modified Fishberg technique."

The purpose of this study is (1) to compare, in unselected hospital cases, the urine concentrations obtained after an injection of surgical pituitrin without a period of water deprivation, with urine concentrations obtained in the same patient following the usual period of water restriction advocated by Fishberg; and (2) to judge the clinical applicability of the pituitrin test.

METHODS

Four procedures were employed:

1. Fishberg concentration test: The technique used was identical with that outlined by Fishberg.[4]
2. Pituitrin concentration test: Without fluid or food restriction the patient emptied his bladder at some designated hour, and 0.5 c.c. of surgical pituitrin (10 units) was injected subcutaneously. Three urine specimens were obtained hourly thereafter.
3. Volhard dilution test: 1,500 c.c. of fluid were administered orally within thirty minutes after emptying the bladder. Four hourly urine specimens were then collected.
4. Procedure 3 was repeated, but in addition 0.5 c.c. of surgical pituitrin (10 units) was injected after the ingestion of the fluid.

The specific gravity of the urine specimens obtained was measured by means of a clinical urinometer calibrated to a standard temperature. Corrections were made for temperature variations[5] and protein content[6] of the urine.

In 100 patients procedures 1 and 2 were carried out. In 25 of these all four procedures were performed.

For the purposes of this study a specific gravity of 1.020 was arbitrarily chosen to divide the cases into two groups. Those patients concentrating to 1.020

*From the Laboratory of the Mount Sinai Hospital, Philadelphia.
Received for publication, June 24, 1942.

or better in any single specimen were considered to have normal renal function, while those not reaching that standard were grouped as representing abnormal renal function. The pitnitrin test was considered to duplicate the Fishberg test when it succeeded in producing a urine which fell into the same group classification as that obtained with the latter.

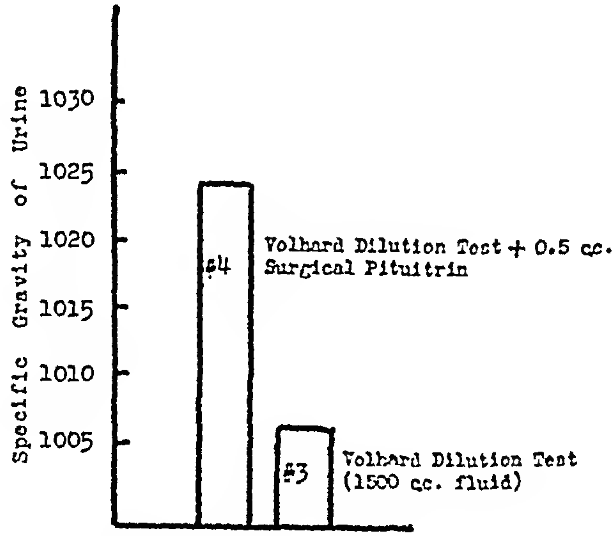

Fig. 1.—Average urine concentration produced by procedures 3 and 4.

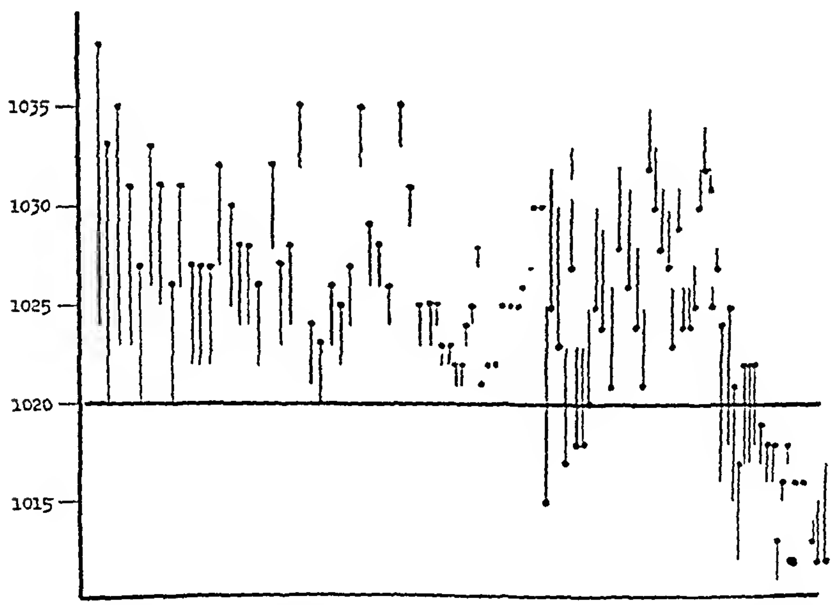

Fig. 2.—A comparison of Fishberg and pituitrin concentration tests of renal function in 100 patients.
• Pituitrin test (procedure[2])—highest concentration.
| Fishberg test (procedure[1])—highest concentration.

RESULTS

In 25 patients the Volhard dilution test (procedure 3) produced a dilute urine in contrast to the definitely more concentrated urine obtained when this

test was combined with the use of pituitrin (procedure 4). The average concentrations obtained are graphically reproduced in Fig. 1.

The pituitrin test compared favorably with the Fishberg test in 90 of 100 cases.

Of 81 patients, comprising a group concentrating to 1.020 or above by means of the Fishberg technique, 4 (4.9 per cent) failed to reach that specific gravity when the pituitrin technique was substituted. Of the 19 patients comprising the group with urine concentrations below 1.020 with the Fishberg technique, 6 (31.5 per cent) showed concentrations over 1.020 with the pituitrin test. These results are graphically represented in Fig. 2.

No deduction can be drawn as to the effect of pituitrin on urinary volume. While on the whole more concentrated urines were accompanied by a reduction in volume, examples were encountered in which alterations in specific gravity were independent of urinary volume.

DISCUSSION

The production of concentrated urines after the injection of 0.5 c.c. (10 units) of surgical pituitrin in the face of a quantity of ingested fluid that ordinarily would have produced a very dilute urine (procedure 3 and 4) definitely established the potency of the preparation of pituitrin used in these experiments.

It is apparent from the results obtained that the pituitrin test duplicated the Fishberg in 90 per cent of the cases investigated.

Of the 10 cases representing failure of correlation of the two tests, in only four did the pituitrin test fail to reach the high concentrations obtained with the Fishberg test. In the remaining six patients the pituitrin technique produced a sufficiently more concentrated urine to alter the estimation of kidney function from abnormal to normal. A clinical and laboratory evaluation of these six cases substantiated the interpretation derived from the pituitrin technique in that there was no history to suggest a latent nephritis, blood pressures were all within normal range, repeated urinalysis revealed no abnormal constituents, and the blood urea clearance tests in each instance were above 80 per cent of normal.

No untoward effects have been observed with the use of pituitrin even in severe hypertensives and in patients with coronary artery disease. We have avoided performing the test in pregnancy.

The technique of the test is simple, causes a minimum of inconvenience to the patient, and by eliminating the need for any specific preparation, permits the physician to exercise more complete control over the patient.

A statistical analysis of the 100 cases* revealed an average difference in specific gravity between the pituitrin and Fishberg tests of -0.001, with a standard deviation of 0.0043. Thus, in any given instance within the statistical limits of ±2 times the standard deviation, the pituitrin test may yield a specific gravity of 0.009 more than, or 0.007 less than, the Fishberg test.

Since the normal kidney can produce specific gravities of greater variation than the abnormal, the cases falling below 1.020 were analyzed separately. These yielded an average difference of +0.002, with a standard deviation of 0.0033.

*Martin S. Abel, M.D.

Thus, in any given instance within the statistical limits of ±2 times the standard deviation, the pituitrin test may yield a specific gravity of 0.008 more than, or 0.004 less than, the Fishberg.

Of the 100 cases, 47 had specific gravities ranging from 1.015 to 1.025. This significant intermediate zone revealed an average difference of −0.0002 and a standard deviation of 0.0029. Thus, values with the pituitrin test can vary from 0.005 more than, or 0.005 less than, the Fishberg in this group.

The analysis further indicates that any given pituitrin test yielding values of 1.025 or above, or 1.015 and below, will almost invariably agree with the Fishberg test. Within the range of 1.015 to 1.025 the probability of the two tests agreeing becomes less, diminishing as the arbitrary dividing line of 1.020 is approached.

However, the analysis presupposes that the Fishberg test is a constant standard and will not vary appreciably from day to day. We demonstrated this basic supposition to be invalid by a survey of 12 patients who revealed a significant day to day variation in specific gravities obtained with the Fishberg technique.

Before the pituitrin test may be accepted as a substitute for the Fishberg on the basis of its technical advantages and 90 per cent correlation revealed in this series, or rejected on the basis of its statistical probability of disagreement with the Fishberg test, one must substitute more substantial criteria for judging the clinical applicability of this new test. This can only come about in the future through long-range observation of patients in whom both tests have been performed.

SUMMARY

1. Surgical pituitrin in the dose used (0.5 c.c. or 10 units) is an active preparation capable of concentrating urine.

2. The substitution of pituitrin for the period of water deprivation used in the Fishberg test resulted in a 90 per cent correlation of the two tests.

3. Absolute failure of the test was encountered in only four cases.

4. In six cases the pituitrin test apparently more accurately reflected kidney function than the Fishberg test.

5. Statistical analysis of the results revealed an appreciable possibility of disagreement between the two tests when specific gravities range from 1.015 to 1.025.

6. A true clinical evaluation of the test will depend upon further comparative studies.

CHEMICAL

THE STANDARDIZATION AND ASSAY OF HEPARIN BY THE TOLUIDINE BLUE AND AZURE A REACTIONS*

Alfred L. Copley, M.D.,† New York, N. Y., and David V. Whitney III, B.S., Chem. E., Kansas City, Mo.

We believe that in view of the increasing use of heparin a direct chemical assay method is of decided advantage. In two previous papers[1, 2] the toluidine blue method of heparin assay (method I) was partially outlined. The present paper is a result of our efforts to increase the accuracy and to widen the scope of this method. In addition, since the biological assay methods for heparin differ greatly in results,[3] it seemed advisable to attempt the standardization of the unit of heparin by employing the colorimetric assay.

The toluidine blue reaction was described by Lison[4, 5] as specific only for sulfuric acid esters of high molecular weight, referring primarily to chondroitin sulfuric acid. Chondroitin sulfuric acid has the amino sugar galactosamine, whereas Jorpes and Bergstroem[6] demonstrated that heparin contains glucosamine. They identified heparin as a mucoitin polysulfuric ester and Jorpes[7] tested it with toluidine blue. Heparin was found to be a mucoitin sulfuric acid residue by Charles and Todd,[8] and these groupings were shown in the analytical values of the sodium salt by Reinert and Winterstein.[9] Barium heparin was shown by Charles and Todd[8] in a recent communication to vary in potency with the sulfur content.

Toluidine blue is not the only dye which gives a metachromatic reaction with sulfuric acid esters, for Conn[10] has shown that toluidine blue is very similar in composition to azure A. Therefore, we undertook to test azure A with regard to its relationship to heparin and in comparison with toluidine blue.

EXPERIMENTAL

We have used the following dyes manufactured by the National Aniline Chemical Company, toluidine blue under the name NU-3, and azure A under the name of NAz-7,‡ as certified by the Commission on Standardization of Biological Stains, Agricultural Experiment Station, Geneva, N. Y. Both products are on the market and, as Dr. Conn has been advised by the manufacturer, they have on hand enough NU-3 recently manufactured to last for about four years.§

*From the Hixon Laboratory for Medical Research, University of Kansas School of Medicine, Kansas City.

Received for publication, April 6, 1942.

†Goldwater Memorial Hospital, Welfare Island, New York.

‡We are indebted to Dr. H. J. Conn for rechecking our sample NU-3 and for supplying us with the sample of Azure A (NAz-7).

§Personal communication, October 29, 1941.

We have been supplied with preparations of heparin by Connaught Laboratories, Lederle Laboratories, and Abbott Laboratories which were assayed biologically by Dr. A. F. Charles, Dr. C. M. Meadows, and Dr. W. C. Risser, respectively.

METHOD I

Procedure.—Make up 1:1,000 toluidine blue (TB) or azure A (AA) by adding 1.6949 Gm. TB (NU-3) to 1,000 c.c. or 1.1494 Gm. AA (NAz-7) to 1,000 c.c. of distilled water. In a series of test tubes place 1 u (Murray-Best unit*), 2 u, 3 u, 4 u, and 5 u of heparin CLT-110 (Connaught Laboratories, Toronto. 1 mg. containing 110 u), make up to 5 c.c. with distilled water, and add 1 c.c. of 1:1,000 toluidine blue (TB). 100 per cent dye strength. Shake, and after standing for fifteen minutes, centrifuge at 3,600 r.p.m. for fifteen minutes. The supernatant fluid is decanted and compared on the Duboscq colorimeter with a solution of 1:6,000 toluidine blue (100 per cent dye strength). The concentrations of dye are computed in gamma. Six cubic centimeters of the 1:6,000 toluidine blue solution contain 1,000 gamma of dye. It has been discovered by experience that those solutions containing from 300 gamma to 700 gamma give the most accurate comparisons. In view of this experience we select those concentrations between these limits for our computations and take the average as our result. After the residual dye concentrations have been computed, they are each substracted from 1,000 gamma (the original dye concentration), giving the amount of dye reacting with the heparin present. Dividing this quantity by the units of heparin in the test, the amount of dye reacting with each unit of heparin is obtained. Dividing the amount of dye reacting with each unit by 150 gives the strength in colorimetric (Copley-Whitney) units.

Results.—In the test on a Connaught Laboratories sample, 110 u per milligram (CLT-110), that we used as a standard, the following concentrations were determined: The 3 u test contained 585 gamma of dye and the 4 u test contained 431 gamma of dye after centrifugation. Subtracting these amounts from 1,000 gamma, the initial concentration, we obtain 415 gamma and 569 gamma, respectively, as the amounts of dye that reacted with 3 u and 4 u of heparin. Therefore, 415 gamma divided by 3 gives 138 gamma of dye reacting with each unit of heparin, and 569 gamma divided by 4 gives 142 gamma of dye reacting with each unit of heparin. The average of 138 gamma and 142 gamma is 140 gamma per unit of heparin. Since the valuation of the Connaught Laboratories appeared to us rather high, and in order to simplify future calculations and standardization, we decided to establish 150 gamma of dye per unit of heparin as the standard. Samples were diluted up to 1 u (Copley-Whitney) per cubic centimeter and tested as in the preceding method.

Three and 4 colorimetric unit tests diluted 1:5 and 1:10 were compared on the K & E spectrophotometer (Fig. 1). Samples of TB 1:10,909 and 1:15,000, diluted 1:5 and 1:10 and compared on the K & E spectrophotometer, were found to approximate the 3 unit and 4 unit tests, respectively. From the above comparisons, 0.15 mg. of 100 per cent TB—TB (NU-3) 59 per cent dye strength as TB; AA (NAz-7) 87 per cent dye strength as TB—were

*Murray and Best[11] fixed the unit of heparin as 0.01 mg. of a crystalline barium salt. The unit of the "pure" sodium heparin, which is based upon the barium salt, equals 1/110 mg.

absorbed by each 1 u of heparin. On comparing subsequent tests on dilute solutions of heparin with standard TB and AA solutions of 1:10,909 = 3 u and 1:15,000 = 4 u in the Duboscq colorimeter, the accuracy was within less than 1 u of heparin provided the heparin solution as stock sample contained less than 30 u per cubic centimeter.

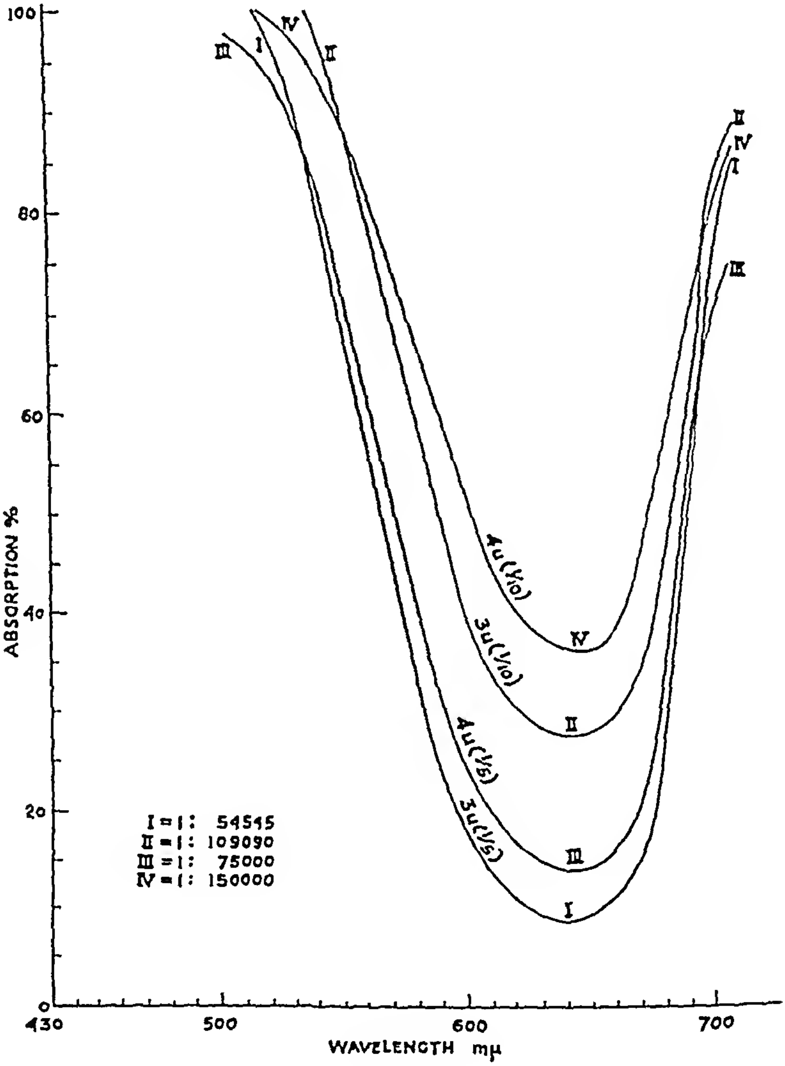

FIG. 1.

In Table I various lots of heparin from different sources were run at the indicated dilutions. These dilutions were calculated to make a solution containing about 1 u per cubic centimeter. The concentrations listed are the averages of three tests each, no concentration varying more than 50 gamma from the average. To arrive at the units per cubic centimeter we subtract the residual concentrations of TB in 3 u and 4 u tests from the original concentration of 1,000 gamma, then divide each by the decolorization value of 1 u or 150 gamma, then divide by 3 u and 4 u, respectively, and average the results. For example, taking

sample No. 1: 3 u = 585 gamma, 4 u = 431 gamma: 1,000 gamma − 585 gamma = 415 gamma, 1,000 gamma − 431 gamma = 569 gamma; 415 gamma ÷ 150 = 2.76 u, 569 gamma ÷ 150 = 3.79 u: 2.76 u ÷ 3 = 0.92 u, 3.79 u ÷ 4 = 0.95 u; 0.92 u and 0.95 u averages 0.935 u.

TABLE I

TABLE II

PHOTOELECTRIC (EVELYN) STUDIES WITH 3 AND 4 COLORIMETRIC UNIT TESTS OF TOLUIDINE BLUE (TB) AND AZURE A (AA)

FILTER NUMBER Mμ	THREE UNITS			FOUR UNITS		
	TB	AA	AVERAGE	TB	AA	AVERAGE
490	60.5	67.5	64.0	67.8	71.8	69.8
520	42.3	48.0	45.2	52.0	57.0	54.5
540	21.0	23.0	22.0	32.0	32.8	32.4
635	0.5	1.5	1.0	1.0	3.8	2.4
660	8.0	15.0	11.5	9.0	18.0	13.5

Center setting = 75. Each value represents average of duplicate tests.

TABLE III

COMPARISON BETWEEN VARIOUS DILUTIONS OF AZURE A OR TOLUIDINE BLUE ON THE EVELYN PHOTOELECTRIC COLORIMETER

FILTER NUMBER Mμ	DILUTIONS OF DYE					CENTER SETTING
	1:6,000	1:12,000	1:15,000	1:18,000	1:30,000	
520	24.0	47.0	55.0	60.5	78.0	75.0
540	7.0	24.5	32.0	38.0	61.0	75.0

From Table II we see that a 4 u test (54.5) equals 1:15,000 dilution (55.0) on Table III at 520 mμ. A 4 u test contains six times 1:15,000 Gm. dye as 100 per cent toluidine blue, since a 4 u test contains 6 c.c. total solution. The decolorization due to 4 u of heparin equals 6 (1:6,000) − 6 (1:15,000) = 36:60,000 = 600:1,000,000 = 600 gamma. Therefore, 1 u heparin decolorizes 150 gamma of 100 per cent toluidine blue.

METHOD II

We have found that in method I there is a possible experimental error of ±50 gamma between triplicate tests. Assuming an error of 40 gamma in testing a solution diluted to 1 c.c. = 1 u, a 3 unit test would leave 590 or 510 gamma, and

a 4 unit test would leave 440 or 360 gamma of dye in solution. If a 3 unit test leaves 590 gamma and a 4 unit test leaves 440 gamma, the value of the solution tested would equal 0.92 u per cubic centimeter. If a 3 unit test leaves 510 gamma and a 4 unit test leaves 360 gamma, the value of the solution tested would equal 1.08 u per cubic centimeter. Referred back to a sample of 100 u per milligram, this would mean an error of ±8 u per milligram. In order to test weighed dry samples in concentrated solution, we developed the following procedure:

Procedure.—A measured portion of the sample is titrated in a beaker with a 1:2,000 solution of TB or AA made up by adding 0.8475 Gm. TB (NU-3) to 1,000 c.c. or 0.5747 Gm. AA (NAz-7) to 1,000 c.c. distilled water. To this solution add 0.05 c.c. increments, with swirling, from a 25 c.c. burette until precipitation starts, allow it to aggregate, and continue to add slowly, drop by drop.

TABLE IV

SAMPLE TITRATIONS WITH 0.05 PER CENT SOLUTIONS OF TOLUIDINE BLUE AND AZURE A

until a distinct blue solution equal to about 1:40,000 TB is observed among the heparin dye flocculation. The titration in cubic centimeters is multiplied by 3⅓ to obtain unitage in colorimetric units. Titration is materially assisted by bottom lighting under the beaker and it is extremely important that the precipitate be allowed to form slowly in order to avoid overtitration. The amount of sample plus titrating solution should not be greater than 75 c.c. at the end point, for, in the course of our work we find that certain concentrations are necessary to produce precipitation of the dye heparin complex. Considerable dilution before adding TB or the addition of TB of too great dilution will prevent precipitation. Various shades of blue mixed with violet will be the result no matter how great the excess of TB or AA over heparin. In titration at considerable dilution the deep violet color of the TB heparin or AA heparin complex masks the end point and makes a sharp end point impossible, except, possibly, a special filter in a photoelectric colorimeter might determine the end point accurately. However, since it is simpler to precipitate the interfering violet at the end point, we choose to do so. We find that a concentration of approximately 1:40,000 of TB or AA is necessary for complete precipitation.

Results.—From tests conducted on samples, we have found that a 100 unit sample of the purest heparin with regard to our reaction yielded a 30 c.c. titration with 1:2,000 TB. Therefore, we arbitrarily set 1 c.c. of 1:2,000 TB equal to 3⅓ u. One cubic centimeter of 1:2,000 TB equals 0.5 mg. TB; therefore, 1 u equals 0.15 mg. (or 150 gamma).

From triplicate titrations of heparin in Table IV it can be seen that a sharp end point is obtained and that the test is reproducible with rather high accuracy (±2 per cent), and over-all accuracy about ±5 per cent.*

In Table V the anticoagulant units and colorimetric units of heparin from various sources are compared.

DISCUSSION

Relationship Between Azure A and Toluidine Blue.—Our results indicate with regard to heparin that a solution of azure A of the same reactive strength as a solution of toluidine blue shows equal chromatic densities at various dilutions. We have found that a solution of azure A that will give, for example, a 30 c.c. titration with a certain sample of heparin when compared with a solution of toluidine blue that gives a 30 c.c. titration with the same sample of heparin will show the same chromatic concentration. Dr. Conn[2a] stated that toluidine blue has not been satisfactorily standardized, and he refers to the formula[11] published demonstrating that its composition is very similar to azure A. In view of the results we obtained, the question arises as to whether the difference between the two dyes is even as much as has been indicated by the published formulas. In this connection it was found that upon standing a shift in the absorption band occurs.[2a] From this Conn concluded that it would appear that toluidine blue can spontaneously change into azure A. However, such a particular chemical change seems to him to be improbable. He feels that there is another, yet undiscovered, explanation for this phenomenon. Old samples of toluidine blue in which this

*All weighings must be to the third significant figure to obtain ± 2 per cent accuracy.

change in color has occurred yielded the same results as azure A. These findings seem to indicate that it might be difficult to standardize any technique that calls for toluidine blue. However, the present toluidine blue (NU-3) of the National Aniline Chemical Company, which has been made in a way different from earlier lots, has to date not shown this change in color absorption. Our sample (NU-3), which was rechecked by Dr. Conn, did not show any change whatsoever in its absorption maximum and agrees entirely in its optical characteristics with the one he has on hand.*

The sample of NU-3 (dye strength 59 per cent) was compared to azure A (NAz-7) and the NAz-7 showed a dye strength of 87 per cent toluidine blue. It would appear that the NAz-7 has, for instance, 13 per cent impurities as compared to 41 per cent in the NU-3. We wonder if an appreciable amount of leuco products is present in the azure A as seems to be in toluidine blue according to information from the manufacturer.[7a] However, we do not know if leuco compounds have any effect upon the thiazins as to causing change in the chromophore group. Both azure A and toluidine blue gave reproducible results with heparin, and thus we feel that these dyes, as standardized by the Commission on Biological Stains, can be used interchangeably.

Comparison of Anticoagulant and Colorimetric Units of Heparin.—By our test the various samples contributed by different laboratories show variation up to 33 per cent of the label value. This suggests that either our test does not measure the anticoagulant value of the sample as a whole, or else the previous tests used were not based on as reproducible conditions as ours. It may be noted that various biological assay methods were used to determine the unit of heparin.†‡ However, the possibility is present that the heparin samples as prepared at the present time do not owe all their anticoagulant power to the heparin compound alone, but may be modified by plasma factors not identified[13] and possibly present in the albumin fraction.[14, 15] An alternative possibility is that there are present in the samples impurities which modify the toluidine blue or azure A reaction. Nevertheless, we feel, since other polysulfuric acid esters of polysaccharides with comparatively high molecular weight exhibit anticoagulant activity[16, 17] and also metachromatic change, as for instance in chondroitin sulfuric acid,[1, 18] they seem to be of similar chemical composition. Our data may not truly represent the physiological activity of the heparin samples, although the results are proportional to the anticoagulant activity as found by various workers. In this connection, a portion of a sample containing about 95 u per milligram was dried to constant weight, heating at 80° C., under low vacuum of 40 mm. and with a slow stream of dry air drawn over the powder. The anticoagulant activity of this portion was found to be 50 u. By comparing the colorimetric titration we found 90 u in the first portion, 77 u in the second. Although the discrepancy between both portions is about 3½ times larger with the biological assay method, the decrease of 13 units with our method is significant. In a test based on physiological standards, such as cat or ox blood, the

*Personal communication, January 16, 1942.

†Dr. Charles used a modification of Howell's method by Charles and Scott.[12] Dr. Meadows used a modification of the method of Reinert and Winterstein.[9] Dr. Risser used a modification of the method of Charles and Scott.[12]

‡Assays employed by Charles, Risser, and Meadows show accuracies as high as ± 5 per cent.

reliability of such a standard is always open to question. According to Jorpes[19] differences of 15 to 20 per cent were demonstrated with his method of standardization with ox blood. There are seasonal changes reported by him. For instance, he found the tendency to coagulation in the summer was at least twice as great as during the winter. Other factors are mentioned by Jorpes which may affect the coagulation time, such as temperature, species, and admixtures of thromboplastin (thrombokinase). Therefore, we feel justified, in view of the indefinite status of the unit of heparin, in establishing a unit on the basis of these reliably reproducible azure A-toluidine blue reactions with heparin.

Colorimetric Unit of Heparin.—We have demonstrated by Tables II and III that a 4 u test of a sample of the Connaught Laboratories containing 110 u per milligram, which exhibited the strongest colorimetric reaction, decolorized 150 gamma per Murray-Best unit. For convenience in computation we have chosen this sample to define the unit of heparin. Therefore, we present the colorimetric unit of heparin equaling the decolorization of 150 gamma of 100 per cent dye content of toluidine blue. It follows that this unit would equal 254 gamma of toluidine blue NU-3 or 172 gamma of azure A NAz-7. We discover in our titration method (method II) that, using 1 u equaling 150 gamma 100 per cent toluidine blue, our results correspond with results obtained by our decolorization method (method I).

SUMMARY

1. The toluidine blue reaction for heparin was developed by use of the Duboscq and Evelyn colorimeters and shown to be practical for assay purposes. The same reaction for heparin was found to be specific with azure A.

2. The relationship between azure A and toluidine blue is discussed. With heparin, azure A yielded 87 per cent dye content as toluidine blue compared to 59 per cent dye content toluidine blue.

3. A titration method of positive value for heparin assay was established which yielded rapid results, reproducible to ±2 per cent, over-all accuracy about ±5 per cent.

4. The comparison between anticoagulant and colorimetric units is discussed.

5. The colorimetric unit of heparin is defined. One unit of heparin decolorizes 150 gamma of 100 per cent toluidine blue dye content. This unit equals 254 gamma of toluidine blue NU-3 or 172 gamma of azure A NAz-7.

We wish to thank Dr. A. F. Charles of Toronto, Dr. C. M. Meadows of Pearl River, N. Y., and Dr. W. C. Risser of North Chicago for supplying us with their preparations of heparin. We also wish to thank Dr. H. J. Conn for his courteous cooperation.

THE QUANTITATIVE ESTIMATION OF GLUCURONATES IN URINE*

WM. DEICHMANN, PH.D., CINCINNATI, OHIO

THE need has long been felt for a reliable quantitative method of estimating glucuronates in urine. Such a method would be of special value in determining the extent of exposure of workmen to any compound which had been found to be detoxified by conjugation with glucuronic acid.

Some of the methods reported in the literature require from eighteen to twenty-four hours for a single analysis (Sauer,[1] Kakinuma[2]); others, based on the formation and distillation of furfural, are disturbed if glucides are present, and are not sufficiently precise in dealing with amounts less than 2 mg. (Tanabe,[3] Fürth and Peschke[4]). Venning[5] employed a gravimetric procedure but obtained only approximately correct results. Florkin,[6] and Maughan, Evelyn, and Browne[7] have developed a quantitative method from Tollens'[8] qualitative naphthoresorcinol test, but single estimations were found unreliable. Recently, Meyer, Block, and Chaffee[9] have reported a method for the estimation of uronic acids in pure solutions.

*From the Kettering Laboratory of Applied Physiology in the College of Medicine of the University of Cincinnati.

Received for publication, July 11, 1942.

Principle of the Method.—The method employed here is also a modification of Tollens' original test, but, in contrast to similar procedures previously reported, it makes use of a preliminary hydrolysis at 75° C., a great excess of naphthoresorcinol, and a hydrochloric acid-naphthoresorcinol mixture heated to 50° C. Further, the final estimation is carried out with a photoelectric spectrometer or with a photoelectric colorimeter.

Experiments have shown that few compounds will interfere in this determination and that an occasional urine sample requires preliminary treatment. If urine contains no pentose or glucose, then the regular procedure is followed. However, if the concentration of pentose is found to be about 0.03 per cent or that of glucose is about 0.3 per cent, the sample analyzed should then be reduced to about 0.1 ml., and when the concentration of these sugars exceeds these limits, the urine samples should then be freed of them prior to hydrolysis. The presence of 1.0 per cent protein or 0.2 per cent ascorbic acid does not interfere. (The normal excretion of ascorbic acid ranges from 30 to 50 mg. in twenty-four hours,[11] which is not in excess of 0.025 mg. in 0.5 ml. of urine. It was found that when 0.5 mg. of ascorbic acid and 0.12 mg. of glucuronic acid were added to a 0.5 ml. sample of human urine, the recoveries of glucuronic acid ranged from 0.124 to 0.132 mg.)

Reagents Required.—Hydrochloric acid (19 Gm. in 100 ml.).

Naphthoresorcinol* (10 Gm. in 100 ml. of 95 per cent ethyl alcohol). This reagent is centrifuged or filtered and will remain stable for five days if kept in a cool place protected from light.

Ether, C.P.

METHOD OF ANALYSIS

(1) *Determining the Need for Removing Interfering Substances.*—The presence of glucose is readily determined by Benedict's qualitative test. Amounts of ascorbic acid sufficient to cause interference may be suspected only in cases of vitamin medication. Testing for pentoses may be carried out by Tollens' test slightly modified as follows: To 1 ml. of urine and 1 ml. of concentrated hydrochloric acid is added 0.1 ml. of 10 per cent naphthoresorcinol in 95 per cent ethyl alcohol. The mixture is boiled for one minute in a test tube with constant shaking, permitted to stand at room temperature for four minutes, cooled under the tap, and extracted with 10 ml. of ether. When the urine is free of pentose, the ether is purple (with the exception of unusual cases that contain no glucuronic acid at all); in the presence of 0.1 per cent pentose the ether is colorless, while intermediate concentrations give various shades of purple. (This unusual behavior seems to result from the speed of reaction of pentose with naphthoresorcinol. The latter appears to be faster than the speed with which glucuronic acid and naphthoresorcinol react. Hence if pentose and glucuronic acid are both present in a sample of urine, pentose will react first, forming a brownish-black ether-insoluble pigment; the absence of color in the ether layer is then due to the fact that the naphthoresorcinol has been used up. The preliminary hydrolysis in the quantitative procedure makes a large amount of "free" glucuronic acid available for immediate reaction. The high concentra-

*Purchased from B. L. Lemke, 248 West Broadway, New York City.

tion of naphthoresorcinol is needed, because this compound reacts not only with glucuronic acid but probably with many impurities; an excess furnishes enough for reaction with the urinary constituents that form ether-insoluble substances and for the reaction with glucuronic acid whereby the purple ether-soluble color is produced. These two factors are mainly responsible for the fact that glucuronic acid can be satisfactorily determined in relatively large urine samples [0.5 ml.] without removal of interfering substances. To study the color, it is best to set up a few specimens of normal urine to which have been added known amounts of arabinose.)

(2) *Removal of Interfering Substances.*—The removal of interfering substances is accomplished by precipitation with lead acetate in slightly acid solution, as suggested originally by Quick,[10] and the precipitation of conjugated glucuronates with basic lead acetate, according to Tollens.[5]

A small quantity (0.2 to 0.4 ml.) of the urine to be tested is measured into a 15 ml. conical centrifuge tube, diluted to 2 ml. with water, and made acid to litmus with 1 to 3 drops of glacial acetic acid. Then, 0.2 ml. of 5 per cent lead acetate is added and the sample is mixed and centrifuged. Tests should be made for complete precipitation of interfering substances by the addition of a drop of lead acetate. If precipitation is found to be incomplete, an additional 0.1 ml. of lead acetate solution is added, the mixture is shaken and again centrifuged. This procedure is repeated until precipitation is complete. The supernatant fluid is poured into a similar centrifuge tube and 0.3 ml. of 10 per cent sodium hydroxide is added. If a precipitate does not form, more sodium hydroxide is added until a permanent precipitate is obtained. Then 3 ml. of the basic lead acetate solution* are added, and the contents are mixed and centrifuged. Tests should be made for complete precipitation of glucuronates by the further addition of a drop of basic lead acetate. When precipitation is complete, the supernatant fluid is discarded and the precipitate is washed by thoroughly stirring it with 10 ml. of water. The mixture is centrifuged again, the supernatant liquid is discarded. The residue is transferred quantitatively, employing 5 ml. of concentrated hydrochloric acid followed by 5 ml. of water, into a 50 ml. graduated cylinder and then incubated for fifteen minutes at 75° C. One milliliter of 10 per cent naphthoresorcinol is added, and the cylinder is allowed to stand for ninety minutes in a water bath maintained at 50° C. After cooling under the tap, the solution is extracted with ether and the remainder of the determination is carried out as described below.

(3) *Analysis.*—(The analysis is started at this point if interfering amounts of glucose, pentose, protein, or ascorbic acid are known to be absent.)

The sample of urine is mixed well, and its total volume is determined. In the case of human or dog urine, 0.3 to 0.5 ml., and of rabbit's urine, 0.2 to 0.4 ml., is then pipetted into a 50 ml. glass-stoppered graduated cylinder and diluted with water to 5 ml. After the addition of 0.2 ml. of 10 per cent hydrochloric acid, the whole is kept for forty-five minutes in a water bath at 75° C.; 5 ml. of concentrated hydrochloric acid and 1 ml. of 10 per cent naphthoresorcinol are then added, and the cylinder is allowed to stand for ninety minutes in a water

*Prepared by heating 10 Gm. of dibasic lead acetate with 200 ml. of water; after boiling and stirring for a few minutes, the solution is allowed to cool and is filtered.

bath maintained at 50° C. After cooling under the tap, the solution is extracted with 10 ml. of ether by shaking the cylinder vigorously for five seconds. After separation into two layers, sufficient ether is added to bring the ether volume to exactly 15 ml., and it is mixed by gently rotating the cylinder. Addition of the second portion of ether will completely clear up any slight turbidity caused by water in the upper layer.

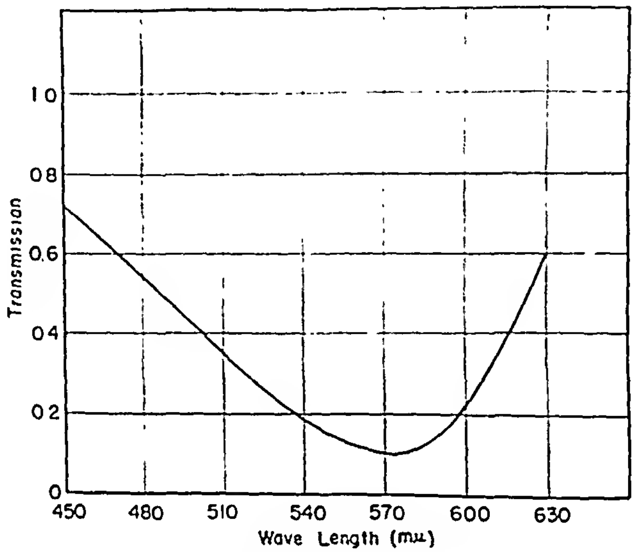

Fig. 1.—Transmission curve of the ether extract.

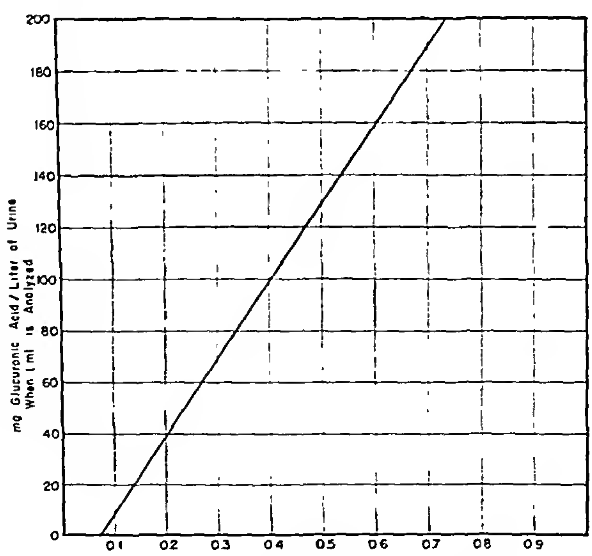

Fig. 2.—Glucuronic acid. Concentration versus density measured with the spectrophotometer at 570 mμ employing 10 mm. matched cells.

(4) *Colorimetric Reading.*—The colored ether is now pipetted into a glass-stoppered flask and is ready for spectrophotometric analysis, which is carried out by using 10 mm. matched cells, with the instrument set at the wave length

of 570 mμ. The final estimation may also be carried out, with equally good results, with a Leitz photoelectric colorimeter employing the green filter No. F-401.

Fig. 1 gives the transmission curve of the pigment formed under the conditions outlined in this procedure.

Fig. 2 gives the relationship between density and concentration of glucuronic acid per liter of urine when the photoelectric spectrometer is employed.

Fig. 3 gives the relationship between concentration of glucuronic acid per liter of urine and readings with the photoelectric colorimeter.

Figs. 2 and 3 were prepared by plotting the readings obtained when known aqueous solutions of pure glucuronic acid (or of a conjugated glucuronate) were analyzed by this procedure.[12]

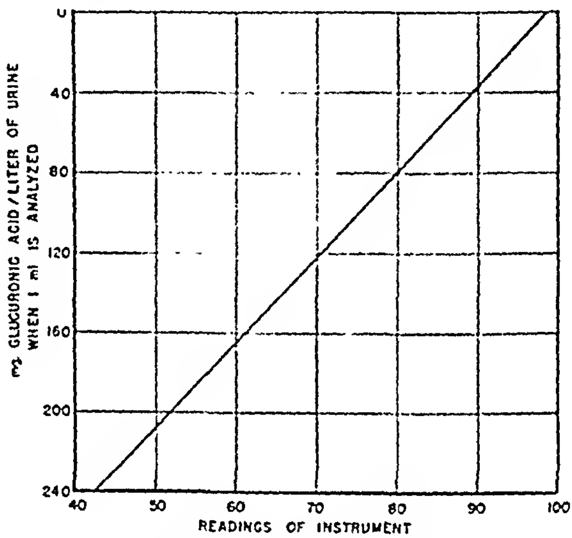

Fig. 3.—Glucuronic acid. Concentration versus reading with the Leitz photoelectric colorimeter with green filter No. F-401.

(5) *Calculation.*—The following example will serve to illustrate the calculation: if 0.25 ml. from a total volume of 280 ml. is analyzed, and a concentration of 70 obtained from Fig. 2 or Fig. 3, then:

$$\frac{70}{1{,}000} \text{ mg.} \times \frac{1}{0.25} \times 280 \rightarrow 78.4 \text{ mg. glucuronic acid/total volume.}$$

(6) *Certain Practical Considerations.*—

(a) The alcoholic naphthoresorcinol solution employed must be *perfectly clear.* The amounts of impurities in this compound vary; it is, therefore, advisable to plot new curves with each new lot of naphthoresorcinol.

(b) The colored ether solution is stable for about one hour; it should be protected from direct sunlight. (Prolonged standing causes an increase in the intensity of the color.)

(c) The analysis must be carried out without delay after the addition of hydrochloric acid. If it should be found necessary to remove interfering substances from the urine, a convenient point to interrupt the analysis comes after the precipitation of glucuronates with basic lead acetate.

(d) An excess of acid lead acetate must be avoided because this will result in loss of glucuronates.

(e) Normal human urine suffers no loss of glucuronic acid when permitted to stand for a week at room temperature without preservatives.

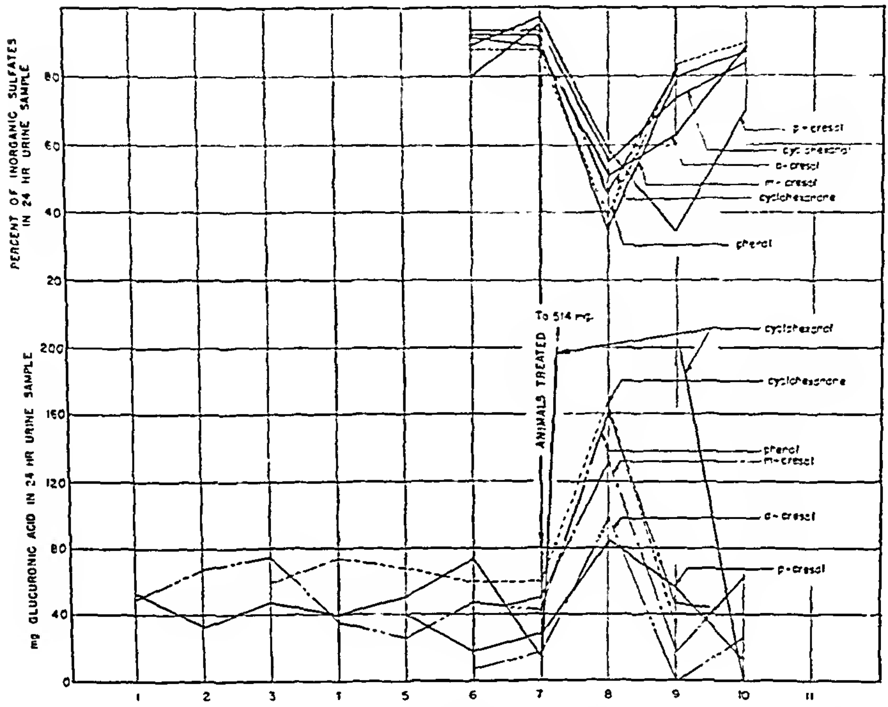

Fig. 4.—Excretion of inorganic sulfates and glucuronic acid in the urine of rabbits following a single oral administration of about half the lethal dose of phenol, o-, m-, and p-cresol, cyclohexanol, and cyclohexanone, respectively.

EXPERIMENTAL

Table I summarizes the recoveries of free and conjugated glucuronic acid added to normal human or rabbit urine and analyzed without previous removal of interfering substances. The recoveries are satisfactory. Table II gives the amounts of free and conjugated glucuronic acid recovered after their addition to urine containing glucose or arabinose; here again the urine was not subjected to preliminary treatment. It can be seen that the presence of 0.03 per cent arabinose or 0.5 per cent glucose does not interfere with recovery of the conjugated compound; the recovery of free glucuronic acid is slightly less complete. Table III shows that following the removal of interfering substances from the urine, as outlined above, 0.25 per cent arabinose added to the urine is removed to a sufficient degree to enable recovery of the conjugated glucuronates; a slight loss of glucuronates is noted, however, when urine contains 0.5 per cent of this pentose. Table IV summarizes the excretion of glucuronic acid in twenty-four-hour specimens from normal men who were under no dietary restrictions. The daily excretions ranged from 65 to 239 mg. These amounts bore no relationship to the total volume of urine excreted. A young dog on a diet consisting

*The urine was not subjected to preliminary treatment because specimens did not contain glucose, pentose, or protein in interfering quantities and the subjects had not received ascorbic acid as medication.

of beef heart and "kibbles" (dried dog food) excreted daily for six days from 24 to 108 mg. of glucuronic acid, and rabbits on a diet of Purina pellets excreted daily for eighteen days from 15 to 75 mg.

Fig. 4 shows the drop in inorganic sulfates and the corresponding increased output of glucuronic acid in rabbits following administration of half the lethal oral dose of phenol, o-, m-, and p-cresol, cyclohexanone, and cyclohexanol, respectively.

SUMMARY

1. A quantitative procedure is presented for the estimation of glucuronates in urine. The method is sufficiently reliable for clinical and industrial use.

2. The daily output of glucuronates for men on an unrestricted diet ranged from 65 to 239 mg. per twenty-four hours. A dog excreted from 24 to 108 mg. and rabbits from 15 to 75 mg. for one-day periods.

3. The administration of about half the lethal oral dose of phenol, o-, m-, and p-cresol, cyclohexanol, and cyclohexanone, respectively, produces, in addition to the well-known drop in the output of inorganic sulfates, a sharp rise in the excretion of glucuronates.

The borneolglucuronic and the mentholglucuronic acids were prepared and kindly supplied by Dr. Armand T. Quick of Marquette University School of Medicine; the glucuronic acid was kindly supplied for these studies by J. R. Harrower of the University of Wisconsin.

THE DETERMINATION OF BROMIDES AND CHLORIDES IN BIOLOGICAL MATERIALS AND AN ACCURATE CLINICAL METHOD FOR DETERMINING BROMIDE IN SMALL AMOUNTS OF BLOOD*

LEON A. GREENBERG, NEW HAVEN, CONN.

IN CARRYING out a series of investigations on the effects of ingested bromides, the needs arose for: (1) a rapid method for determining accurately both bromides and chlorides in a single wet sample of tissue or blood; and (2) a rapid and reliable clinical method for determining the concentration of bromide in 0.1 c.c. of blood as drawn from a needle prick. Trial of the various methods for determining bromides and chlorides reported in the literature showed that none fully satisfied these needs. Two procedures which did satisfy them were, therefore, developed and are reported here. The findings from analyses made on predetermined amounts of bromide and chloride are given to show the accuracy of the methods and in addition the results from a series of determinations on the comparative bromide content of whole blood and serum.

All determinations of bromide in biological material are carried out in two stages: (1) the treatment of the material to obtain the bromide in a form and medium suitable for estimation; and (2) the estimation of the bromide. Three general methods are available for carrying out the first stage: (1) deproteinization; (2) destruction of the dried organic material by alkaline ashing; and (3) destruction by acid digestion.

TREATMENT OF MATERIAL

Deproteinization can be applied only to fluids; it imposes limitations also on the methods for estimating the bromide. It has been used for the electrometric titration and colorimetric estimation of bromide in blood, serum, and cerebrospinal fluid, but not previously for direct chemical estimation, as in the clinical method to be described later.

Alkaline ashing is the treatment most commonly used. A review of the literature shows, however, that it has given unsatisfactory results in the hands of many investigators. The method in general requires the use of dried material and is open to errors from spattering, overheating, and transfer of materials. Neufield[1] has described a modification of the Francis and Harvey method with which he obtained accurate recoveries, but the procedure required six to eight hours for a single determination. Brodie and Friedman[2] have used a type of ashing described by Kendall[3] and report that a complete determination may be made in about two hours with accurate recoveries. In this laboratory we have not been able to obtain consistently accurate results with alkaline ashing procedures.

*From the Laboratory of Applied Physiology, Yale University, New Haven, Conn.
Received for publication, July 15, 1942.

Acid digestion, except in the form of the closed Carius[4] procedure, has been used much less commonly than the alkaline ashing. It has the advantage that it is a wet digestion and it is rapid. It has, however, the particular disadvantage that the bromide must first be converted to an insoluble salt to prevent loss and then after the digestion reconverted to soluble bromide for estimation. Hartner,[5] failing to obtain satisfactory results with alkaline ashing, used concentrated nitric acid in the presence of silver nitrate. He converted the silver bromide to soluble bromide by treatment with zinc and sodium sulfide. Doering,[6] using the closed Carius method, found that this conversion was not always quantitative and employed zinc only. The procedure took many hours and any advantage of speed of the acid digestion over the alkaline ashing was lost. The procedure to be described in the next section as a laboratory method for the determination of bromide and chloride in tissue employs acid digestion but successfully overcomes the slow conversion of the silver halides with zinc by dissolving them in sodium thiosulfate solution and recovering the soluble bromide.

ESTIMATION OF BROMIDE

Four methods, each with various advantages and disadvantages, are commonly used for estimating bromides after treatment of the material: (1) colorimetric determination; (2) electrometric titration; (3) the liberation and estimation of bromide; and (4) the oxidation of the bromide to bromate and determination by iodometric titration.

For colorimetric determination of bromide the reagents used have been fluorescein,[7] fuchsin,[8] and gold chloride.[9] All colorimetric methods have proved poor because of their lack of sensitivity, inaccuracy, and nonspecificity. A method using gold chloride first described by Walter[9] and later modified by Wuth[10] and by Diethelm[11] has, in spite of its inaccuracy and unreliability, been used in many clinical investigations because of its simplicity.

Electrometric titration of bromide requires either that the bromide be present in concentrations approximating that of chloride present or the preliminary removal of most of the chloride. Its usefulness is correspondingly limited.

Several methods have been described for the oxidation of bromide to free bromine.[12-14] All of them necessitate an exact regulation of conditions to avoid the simultaneous formation of chlorine, incomplete oxidation of bromides, or loss of bromine.[1] All the procedures are time-consuming.

The oxidation of bromide to bromate is quantitative in the presence of chloride and the procedure for carrying it out is rapid and simple. The method originating with van der Meulen,[15] and modified by Kolthoff and Yutzy,[16] involves the oxidation of bromide to bromate by the use of hypochlorite according to the reaction:

$$3\ ClO^- + Br^- = BrO_3^- + 3\ Cl^-.$$

After the oxidation is complete, the excess hypochlorite is reduced with sodium formate. The addition of iodide to the bromate in acid solution results in the liberation of six equivalents of iodine, thus giving a sixfold increase in sensitivity over methods in which the bromine is titrated directly. This oxidation procedure has been used successfully by Dixon[17] and by Brodie and Friedman.[2]

LABORATORY METHOD FOR DETERMINING BROMIDE AND CHLORIDE IN BIOLOGICAL MATERIALS

The method described here has proved to be rapid and highly accurate; it avoids many difficulties inherent in methods previously described and permits the determination of both bromide and chloride on a single sample of material. The material is digested with nitric acid in the presence of a known quantity of silver nitrate. The digestion requires about fifteen minutes. The fluid containing the excess of silver nitrate is separated from the precipitate of silver halides and is titrated according to the procedure of Volhardt; from the value obtained the total halogen content of the material is calculated. The precipitate of silver halides is then dissolved in a solution of sodium thiosulfate; the thiosulfate is destroyed and its products are removed by heating with hydrochloric acid in the presence of metallic zinc. Metallic silver is precipitated. The dissolved zinc is precipitated with sodium carbonate and the filtrate contains all the halides in the form of sodium salts. The bromide is then oxidized by the method of Kolthoff and Yutzy[16] and the bromate is determined iodometrically. The detailed steps of the analytical procedure are as follows:

To the weighed sample (about 1 Gm.) of biological material in a 125 c.c. Erlenmeyer flask there are added exactly 3 c.c. of 0.05 N silver nitrate solution in concentrated nitric acid and also 25 c.c. of concentrated nitric acid. The mixture is placed on a hot plate for fifteen minutes for digestion. Saturated potassium permanganate solution is then added, drop by drop, until its color persists for several minutes; a few drops of 20 per cent sodium oxalate solution are added to remove the excess permanganate. The flask is then cooled under water flowing from a tap and placed in a rack so tilted that the precipitate of silver halides settles in a small area. The clear supernatant fluid is decanted into a second Erlenmeyer flask; the precipitate is washed twice with 10 c.c. of water from a washing bottle and the decanted fluid is added to that in the second flask. The silver nitrate in this fluid is titrated with thiocyanate and ferric alum after the method of Volhard.[18] The silver nitrate, as determined, when subtracted from that added, gives the total halide content of the material under analysis.

The bromide in the precipitate is then determined as follows: The precipitate is dissolved in 2 c.c. of 20 per cent sodium thiosulfate solution. Twenty cubic centimeters of distilled water are added and 10 c.c. of N hydrochloric acid and the mixture is boiled for five minutes. The flask is then removed from the hot plate and a pinch of powdered zinc is added; the mixture is then boiled vigorously for three minutes to remove the hydrogen sulfide formed. The flask is then removed from the heat and 5 c.c. of 20 per cent potassium carbonate are added to the solution which is then cooled and washed into a volumetric container to 50 c.c. volume. The solution is then filtered and 40 c.c. of the filtrate are placed in a 125 c.c. Erlenmeyer flask.

By the above procedure the silver bromide is converted to a soluble bromide which is then estimated by conversion to bromate followed by iodometric titration after the general procedure of Kolthoff and Yutzy as follows: 2 N hydrochloric acid is added until the acid is in slight excess. Approximately 2.5 Gm. of sodium dihydrogen phosphate and 6 c.c. of sodium hypochlorite solution (1 N in 0.1 N sodium hydroxide) are added, and the mixture is boiled gently for five min-

utes. Five cubic centimeters of 50 per cent sodium formate solution are added. The mixture is then boiled vigorously for five minutes and cooled, after which 5 Gm. of sodium dihydrogen phosphate, 20 c.c. of 2 N hydrochloric acid, 3 drops of 10 per cent ammonium molybdate solution and 1 Gm. of potassium iodide are added. The liberated iodine is titrated with 0.005 N thiosulfate; the titration is completed in the presence of 5 c.c. of 1 per cent starch solution. A blank determination is run whenever new reagents are made up, and the volume of thiosulfate used in this titration is subtracted from that used in analysis. Each cubic centimeter of thiosulfate is equivalent to 66.6 micrograms of bromine in the material used for analysis.

In Table I are given the results from a series of 24 determinations made on four different aqueous solutions containing known amounts of bromide and chloride. The range of errors for bromide is +0.006 to −0.009 mg. and the algebraic mean is −0.00015; the corresponding values for chloride are +0.04, −0.04, and −0.004.

In Table II are given the results from a series of 12 determinations made on single specimens of blood to which known amounts of chloride and bromide were added. The amount of bromide and chloride in the blood before addition was taken as the average for six determinations. The range of error for bromide is +0.004 to −0.008, and the algebraic mean is −0.0015.

In Table III are given the results of triplicate analyses made on various tissues of an animal previously given sodium bromide. The range of errors in any one series of determinations is 0.005 mg. for bromide and 0.03 mg. for chloride.

CLINICAL METHOD FOR DETERMINING BROMIDES

Many procedures described in the literature for the determination of bromide in blood are called micromethods. "Micro" as used in these instances refers to the minute amounts of bromide estimated and not the amount of blood used for the analysis. To the clinician, however, a micromethod is usually one by which clinically important concentrations of the substance being estimated can be determined on a "micro" sample. The methods previously reported for estimating the bromide in blood require 3 to 10 c.c. and hence necessitate venepuncture, and even with these large samples the clinical methods ordinarily employed are so inaccurate as to render them little more than indicators of the general magnitude of the bromide present. The method described here requires only 0.1 c.c. of blood which can readily be obtained by puncture of the

skin of the finger tips or ear lobes. The general procedures consist in deproteinization of the blood, the oxidation of the bromide in the filtrate to bromate, and the iodometric titration of the bromate. The procedure in detail is as follows:

The 0.1 c.c. of blood is discharged directly from the pipette in which it is drawn into 6.5 c.c. of 0.45 per cent zinc sulfate solution in a test tube. One-half cubic centimeter of 0.1 N sodium hydroxide solution is then added and the tube is shaken, placed in a boiling water bath for three minutes, and then cooled. The fluid is next filtered and 5 c.c. of the filtrate are placed into a second test tube. There are then added in succession, 0.3 c.c. of 2 N hydrochloric acid, 1 c.c. of calcium hypochloride solution,* and a pinch of calcium carbonate. The carbonate should be slightly in excess, as indicated by its persistence as a precipitate. The tube is then placed in a boiling water bath for eight minutes, after which 0.4 c.c. of 20 per cent sodium formate solution is added, and the tube is heated for eight minutes more. The tube is then removed from the bath and cooled. There are added in succession 3 c.c. of 2 N hydrochloric acid and 1 c.c. of 10 per cent potassium iodide solution. The tube is shaken and 0.5 c.c. of starch solution is added. The contents are then titrated with 0.0004 N sodium thiosulfate solution. A blank determination is made whenever new reagents are prepared: the blank ordinarily ranges between 1.0 and 1.7 c.c. of thiosulfate and should be subtracted from the volume of thiosulfate used in analysis. Each cubic centimeter of 0.0004 N thiosulfate corresponds to 7.6 mg. per 100 c.c. of bromide or 9.5 mg. per 100 c.c. of sodium bromide in the blood upon which the determination is made.

In Table IV are given the results of a series of 50 determinations made on blood (containing less than 0.05 mg. per 100 c.c. of sodium bromide) to which amounts of sodium bromide, ranging from 50 to 300 mg. per 100 c.c., had been added. The range of absolute errors is fairly constant for all concentrations of bromide and is +6 to −5 mg. per 100 c.c.; the percentage error, therefore, de-

creased correspondingly with the increase in concentration. At 25 mg. per 100 c.c. in the blood the maximum error was 12 per cent, at 100 mg. per 100 c.c., 5 per cent, and at 300 mg. per 100 c.c., 2 per cent. Such errors are of no clinical significance, particularly as concentrations below 100 mg. per 100 c.c. rarely have clinical importance. In addition to the series of determinations shown in Table IV, analyses were made of the bromide content of the blood of 120 subjects known to have taken no bromide medicinally; the concentrations found ranged from 0 to 5 mg. per 100 c.c., values of no clinical importance. A total of more than 11,000 determinations have been made with the clinical method described and the majority in duplicate with no indications of error beyond the ranges given here.

CONCENTRATION OF BROMIDE IN WHOLE BLOOD AND SERUM

The concentration of bromide is ordinarily recorded clinically as sodium bromide in the serum. The method as described here is applied to whole blood. The analytical method is entirely applicable to serum, but the use of whole blood does away with the necessity of drawing large samples of blood. The concentration of bromide in the serum is somewhat greater than in the whole blood, since, as with chloride, there is less bromide in the corpuscles than in the serum. The difference is, however, slightly less than for chlorides[19]; the relation appears to be approximately 1:0.7. In the clinical determination of bromides even a considerable variation in the number of red blood cells would not introduce a large error. Thus with a bromide distribution of 0.7, 100 mg. per 100 c.c. of bromide in whole blood would at a hematocrit reading of 50 indicate a serum of 118 mg. per 100 c.c.; at 40, 114 mg. per 100 c.c.; at 30, 110 mg. per 100 c.c.; and at 20, 106 mg. per 100 c.c.

A series of determinations was made to relate the concentrations of bromide in serum and whole blood. One hundred and thirty-one analyses were made of blood and serum on 50 different subjects who were receiving, or had recently received, bromide and showed concentrations in the blood ranging between 25 and 190 mg. per 100 c.c. Blood was drawn by venepuncture, oxalate was used as an anticoagulant, and a specimen of the whole blood and of the serum obtained from it were analyzed for bromide. The ratio of bromide in whole blood to that in serum averaged 0.88, with extremes of 0.94 and 0.87. Thus the concentration of bromide in whole blood was approximately 12 per cent less than in serum. Conversion can be made by multiplying the results obtained from whole blood by 1.14 without introducing an error of much more than ±4 per cent. In the extreme instance as that calculated above from the assumed distribution between serum and corpuscles in marked anemia (hematocrit reading 20), the error would be increased to approximately 8 per cent.

CONCLUSIONS

1. The principles of determining bromides in biological materials are discussed critically.

2. A rapid and accurate method is described for determining both bromides and chlorides on a single sample of blood or tissue. Acid digestion is used and the silver halides are converted to soluble halides by treatment with thiosulfate.

3. A rapid and reliable clinical method is described by which bromide can be determined directly in 0.1 c.c. of blood drawn from a needle prick. The method is more accurate than any clinical method previously described and avoids the necessity for venepuncture.

THE DETERMINATION OF DEMEROL IN URINE WITH PRELIMINARY OBSERVATIONS ON ITS EXCRETION IN MAN*

ROBERT A. LEHMAN, PH.D., AND THEIS AITKEN, M.S.
NEW YORK, N. Y.

CONSIDERABLE interest has arisen concerning the analgesic and antispasmodic properties of demerol which is the hydrochloride of 1-methyl-4-phenyl-piperidine-4-carboxylic acid ethyl ester. A number of reports have already appeared concerning its action on various physiologic functions, both in animals and in man.[1-8] To facilitate the study of the fate and manner of disposal of demerol in the animal body a method is suggested for determining demerol in urine, and some preliminary data are included on the urinary elimination of the drug in man.

The method depends upon the formation of a benzene-soluble compound between the free base of demerol and the dye bromthymol blue (dibromthymolsulfonphthalein) in an equimolar ratio. The free base is first extracted from the urine with benzene at pH 7.5. The resulting benzene solution of demerol is then shaken with an aqueous solution of the dye, also buffered at pH 7.5, whereupon an amount of dye approximately equivalent to the amount of demerol is carried into the benzene as a yellow compound.† This compound is readily decomposed so that the sodium salt of bromthymol blue may be extracted by aqueous alkali while the free base of demerol remains in the benzene and is discarded. The amount of dye extracted may be determined colorimetrically, and thus, indirectly, the original concentration of demerol.

PROCEDURE

The following solutions are required:

1. Concentrated buffer solution: 3.68 Gm. of $NaH_2PO_4 \cdot H_2O$ and 38.2 Gm. of $Na_2HPO_4 \cdot 12\ H_2O$ are dissolved in distilled water and made up to one liter.

2. Dilute buffer solution: 250 c.c. of solution 1 is diluted with an equal volume of distilled water.

3. Stock bromthymol blue solution: 0.400 Gm. of bromthymol blue (Eastman) is dissolved with warming in 30 c.c. of water and 6.4 c.c. of 0.100 N sodium hydroxide and made up to 100 c.c.

4. Dilute bromthymol blue solution: Solution 3 is diluted 1:5 with distilled water.

5. Buffered bromthymol blue solution: 40.0 c.c. of solution 4 are made up to 100 c.c. with solution 2.

The first operation is to buffer the urine to approximately pH 7.5. For this purpose a preliminary test is made. A drop of the stock bromthymol blue solu-

*From the Department of Therapeutics, New York University College of Medicine.
Received for publication, June 29, 1942.

†We are indebted to Dr. O. W. Barlow and Dr. D. R. Climenko for suggesting the application of this principle to the determination of demerol.

tion is added to a mixture of 10 c.c. of concentrated buffer solution and 10 c.c. of the urine to be analyzed. The color of the resulting solution should be greenish blue to blue. If it is yellowish green to green, about 0.5 N sodium hydroxide solution is added drop-wise from a burette until the greenish-blue shade is produced. The indicated amount of sodium hydroxide is later added, in addition to the buffer, to fresh 10 c.c. aliquots of urine for analysis. If the urine contains a suspended precipitate, as is often the case, the test mixture should be centrifuged and the color of the supernatant liquid observed.

Three 250 c.c. separatory funnels are required for each determination. Ten cubic centimeters of concentrated buffer solution, 10 c.c. of the urine to be analyzed, and the proper amount of 0.5 N sodium hydroxide, as determined by the preliminary test, are placed in the first funnel, and enough water is added to bring the volume to 25 c.c. The demerol is extracted from the aqueous layer by shaking for thirty seconds with 60 c.c. of benzene. The aqueous layer is drained into the second funnel while the yellow benzene layer is decanted through the neck into the third funnel which must be dry.* The extraction is repeated twice with 50 c.c. portions of benzene, which are added to the first extract. The combined extracts are then shaken for two minutes with 25 c.c. of buffered bromthymol blue solution. The aqueous layer is drained into a flask and the benzene layer is decanted into a dry Erlenmeyer flask. The bromthymol blue solution is returned to the same funnel and is shaken gently with 35 c.c. of fresh benzene. Too vigorous shaking will result in an emulsion which separates only after long standing. The aqueous layer is now discarded, and the benzene extract is combined with the main portion which is allowed to stand until crystal clear. One to two hours is usually sufficient. The combined benzene extract is now decanted into a clean separatory funnel and extracted twice with 40 c.c. portions of 0.05 N sodium hydroxide solution, and the combined alkaline extracts are made up to 100 c.c. with 0.05 N sodium hydroxide. However, if the amount of demerol present in the original 10 c.c. of urine did not exceed 0.1 mg., it is preferable to extract the benzene solution with two 20 c.c. portions of 0.05 N sodium hydroxide and make the combined extracts up to 50 c.c. With practice, one can readily tell from the depth of yellow color in the benzene whether or not the amount of demerol in the original 10 c.c. of urine was greater than 0.1 mg.

The percentage transmission of the blue solutions is determined in a photoelectric colorimeter using a Corning filter combination of No. 350 (H.R. Traffic Yellow) and No. 398 (Dark Aklo).† The amount of demerol in the original 10 c.c. of urine is then determined by reference to a curve (Fig. 1) relating the log percentage transmission of the final blue solutions to the milligrams of demerol per 10 c.c. of urine. This curve was obtained by analyzing 10 c.c. aqueous samples containing appropriate amounts of demerol in place of urine in ex-

*In order to obtain benzene solutions practically free of the aqueous solution, each separation throughout the procedure is made as follows: the aqueous layer is drained through the stem of the funnel, and the funnel is rotated briskly to bring about a further separation of aqueous solution which, together with the major portion of any emulsion formed at the interface, is also drained through the stem. The benzene is then decanted through the neck of the funnel in such a way that traces of emulsion clinging to the sides of the funnel are retained on the walls.

†The absorption maximum of an alkaline bromthymol blue solution occurs at 6,170 angstrom units. This filter combination cuts off sharply at 5,400 angstrom units. Other combinations of filters were tried but none gave a steeper or more nearly linear curve of Beer's law.

actly the procedure described above. It will be seen from Fig. 1 that the curve follows the Lambert-Beer law in the range zero to 0.400 mg. of demerol, and deviates only slightly over the rest of the range.

It would appear that a curve based directly upon standard solutions of bromthymol blue might be used rather than the empirical curve (Fig. 1) for which each point must be obtained by the complete extraction process. This is not the case, however, because the theoretical amounts of bromthymol blue are obtained only approximately in the extraction process. The per cent of the actual amount of bromthymol blue obtained in the final extract to the theoretical amount expected was found to change progressively with the demerol content

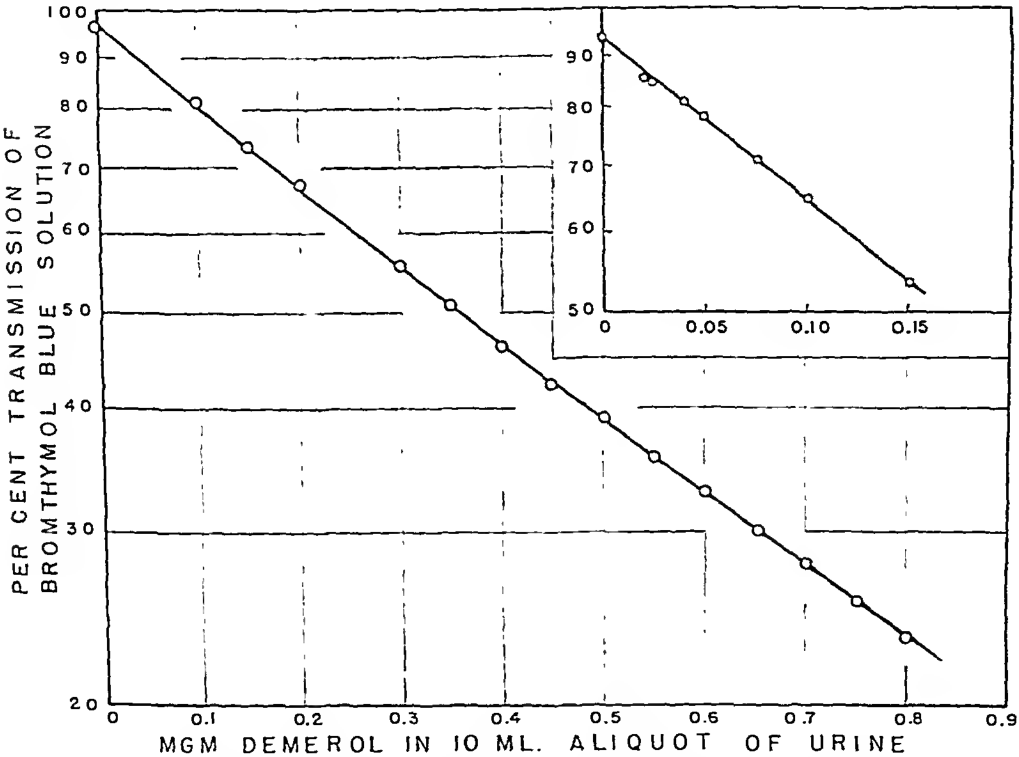

Fig. 1.—Relationship between the percentage transmission of bromthymol blue solution and the amount of demerol present in the original 10 c.c. sample of urine or aqueous solution. The inset shows the same relationship in the case where the final bromthymol blue solution has been diluted to 50 c.c. instead of 100 c.c.

of the original aqueous solution, as shown in Table I. The probable reasons for this deviation from theoretical are: (1) incomplete extraction of demerol base in the first step of the procedure; (2) loss of demerol into the aqueous layer in the second step, this being governed by the concentration of the excess dye, which, of course, is dependent upon the concentration of demerol; (3) extraction by the benzene layer of some uncombined dye present as a result of hydrolysis of sodium bromthymol blue in the buffered solution, the amount, which is small, being directly proportional to the amount of dye and indirectly proportional to the amount of demerol; and (4) the mechanical transfer of dye in the last step of the procedure. The curve does not pass through the origin, due to reasons (3) and (4).

RESULTS

Recoveries of demerol from aqueous solutions are shown in Table II. When the procedure was first applied to urine, it was noted that fresh alkaline urines (twenty-four-hour specimens) have a considerable blank, or apparent demerol concentration, while fresh acid urines have little or none. Old urines which have become alkaline on standing also show a blank. Since blanks occur in alkaline urines and not to any great extent in acid urines, it seems likely that the blanks are due to basic decomposition products. In order to study this factor a urine containing a known amount of demerol was aged under various conditions to show the effect of inhibiting decomposition with mercuric chloride, of allowing decomposition to occur normally, and of facilitating it by making the urine alkaline. Table III shows the results of this study. The demerol content of the portion of urine preserved with mercuric chloride did not change during the ten-day aging period, while the untreated portion had an apparent demerol

concentration of nearly twice the original value, and the portion made alkaline showed more than twice the original value.

Many organic bases react similarly to demerol, and the presence of such compounds in the urine will give rise to a blank or apparent demerol content. Quinine, codeine, aminopyrine, ephedrine, and nicotine have a demerol-like reaction, and it is likely that many other alkaloids do also. Morphine, however, in amounts likely to be present in the urine does not interfere seriously with the de-

termination of demerol, since 10 mg. of morphine sulfate give an apparent demerol concentration of only about 0.1 mg.

Table IV shows recoveries of demerol added to normal twenty-four-hour urines which were collected in bottles containing 20 c.c. of saturated mercuric chloride solution from 13 subjects receiving no drugs.

In order to determine the order of magnitude of the excretion of demerol, the drug in total doses of 100 to 200 mg. daily was administered to three subjects, and the twenty-four-hour urine specimens were analyzed by the method just described, using mercuric chloride as a preservative. The results are shown in Fig. 2. The data have been plotted in terms of per cent of the total administered demerol which had been recovered in the urine at any given time. It will

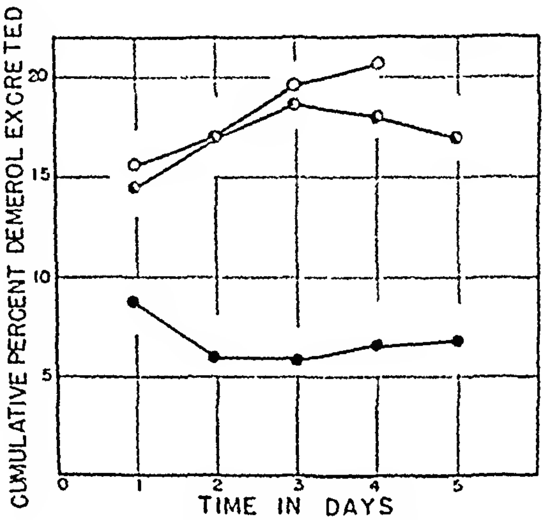

Fig. 2.—Excretion of demerol after oral administration of 100 to 200 mg. daily.

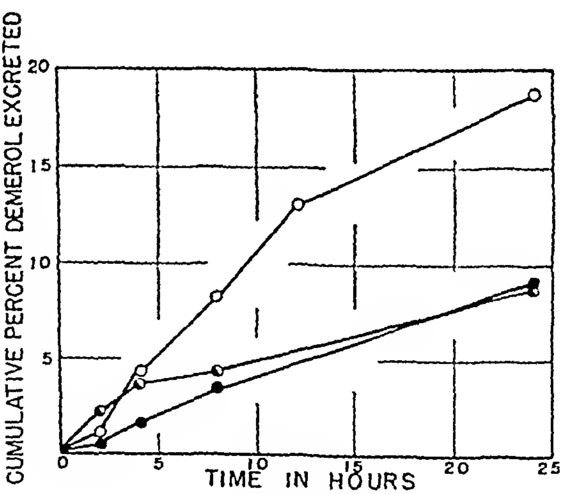

Fig. 3.—Excretion of demerol after subcutaneous injection of 100 mg.

be seen that, roughly, 5 to 10 per cent of the demerol is eliminated daily. To test the possibility that the demerol remaining unaccounted for may have escaped absorption in the intestinal tract, 100 mg. were administered subcutaneously to each of three subjects, and the urine was analyzed at intervals for the first twenty-four hours. The results of this study are shown in Fig. 3, and they agree in order of magnitude with those in Fig. 2. Thus, of 100 mg. injected, about 5 to 20 per cent has been excreted at the end of twenty-four hours. From

the agreement between the two routes of administration it seems probable that incomplete absorption is not accountable for the demerol which fails to appear in the urine.

SUMMARY

A method has been described by which demerol can be determined in amounts from 0.05 to 0.7 mg. per 10 c.c. of aqueous solution, with an average error of 0.9 per cent. The recoveries from urine indicate that amounts of demerol between 0.08 and 0.4 mg. per 10 c.c. (8 to 40 mg. per liter) can be determined, with an average error of 2.7 per cent. In no case did the error exceed 10 per cent.

Basic products resulting from the aging of urine cause a blank or apparent demerol concentration. Mercuric chloride prevents the formation of such products, and it is essential that it be used routinely in the collection of specimens.

The presence of various alkaloids in the urine interferes with the determination of demerol and care should be exercised accordingly in analyzing specimens when the subject has received other medication. Morphine does not interfere.

Preliminary excretion studies have been reported on six subjects who received therapeutic doses of demerol.

BOOK NOTICES

Anoxia*

DR. VAN LIERE who has contributed a great deal to the subject of anoxia writes with justified authority. His book is primarily a discussion of the altered physiology of anoxia as it affects blood, tissues, cells, and the various body systems. There are relatively short chapters on mountain sickness and altitude sickness and acclimatization.

The volume will be of especial interest in aviation medicine, physiology, and biochemistry, and a helpful reference work for the clinician.

The Lymphatic System†

THE LYMPHATIC SYSTEM is a series of five lectures given at Stanford University in 1941. Dr. Drinker's first lecture discusses the evolution of the mammalian circulation. His second lecture is on the development and characteristics of the capillary circulation. The third lecture deals primarily with the lymphatic system. In the fourth, he discusses normal and abnormal physiology of the body fluids. The final lecture deals with practical problems in medicine and surgery.

Written by a world authority on the lymphatic system, this is essentially a practical summary which should be of value both to laboratory investigators and clinicians.

The Doctors Mayo‡

IT WAS to be anticipated that a biography of the Mayos, father and sons, would appear reasonably soon after the death of the last of this famous trio. These men represented the greatest achievement of private group practice that the world will probably ever see. While group practice will continue, it will undoubtedly be taken over increasingly by the state as a public service.

The contents of this book are sponsored by the University of Minnesota and are authentic. The volume is a little long for easy reading, but the most interesting part is the first half which describes the earlier formative years of the Mayo Clinic. The latter part of the book can be skimmed, and with considerable profit to the reader.

Manual of Clinical Chemistry§

REINER'S *Manual of Clinical Chemistry* is a small "pocket" book containing adequate directions for performing nearly all the clinical chemical examinations that are likely to be called for in hospital laboratories. Included are quantitative tests for the various hormones and vitamins; also toxicological tests, arsenic, lead, mercury, and barbiturates. There is one error of a decimal point on page 5 which, however, does not invalidate any of the procedures described in the book.

*Anoxia. Its Effect on the Body. By Edward J. Van Liere, Ph.D., M.D. Cloth, 269 pages, $3.00. The University of Chicago Press, Chicago, Ill., 1942.

†La[illegible] The Lymphatic System. Its Part in Regulating Composition and Volu[illegible] By Cecil K. Drinker, Professor of [illegible] of the School of [illegible]vard University. Stanford Univers[illegible] iversity Series, M[illegible] V, No. 2. Cloth, 101 pages, $2.25. [illegible] Press, Stanford [illegible] 1942.

‡The Doctors Mayo. By Helen Clapesattle. Cloth, 822 pages, $3.75. The University of Minnesota Press, Minneapolis, 1941.

§Manual of Clinical Chemistry. By Miriam Reiner, M. Sc., Assistant Chemist to the Mt. Sinai Hospital, New York. Introduction by Harry Sobotka, Ph.D., Chemist to the Mt. Sinai Hospital, New York. Cloth, 296 pages, with 18 illustrations, $3.00. Interscience Publishers, Inc., New York, 1941.

Neuroanatomy*

DR. METTLER'S book is primarily a student text. The first portion deals with gross anatomy; the second, with microscopic anatomy. The book is so organized that when the medical student who has used it in his first year anatomy reaches his third and fourth year work in clinical neurology, he will find it a very handy reference volume. It is abundantly and well illustrated.

Pediatric Gynecology†

SIXTEEN years ago Dr. Schauffler, faced with a clinical problem of disease involving the genitals in a female child, found to his surprise that discussions of the general subject in the medical literature were few and rather noninformative. The present volume presents the results of his studies in the ensuing years. It is entirely a clinical book. It deals with methods of examination and treatment of disease of the sexual organs and other pelvic pathology in female children. The discussion carries on through abnormalities of adolescence. Diseases discussed include vaginitis, pelvic peritonitis, enuresis, pyelitis, rectal pathology, dysmenorrhea, and a large number of other conditions. There are sections on social service aspects of the treatment and supervision of these children; also on medicolegal aspects, in which is included a discussion of rape. The appendix includes lists of standard hormone preparations.

The work is practical and authoritative.

The Physiology of Domestic Animals‡

THE Physiology of Domestic Animals will be of greater use to veterinary physicians than to those dealing with human disease. However, it will be of distinct value to those who are interested in comparative physiology and to those in the field of experimental medicine who deal with animals in their work.

Methods of Treatment§

IT WOULD be rather difficult to furnish "an outline of all the methods of treatment in internal medicine" in a single volume of less than a thousand pages. Dr. Clendening has gone far toward accomplishing this. In succeeding editions the coverage has been increasingly complete. Naturally, the space devoted to any one subject is decidedly limited and the treatment is at times superficial. However, the volume serves very nicely as an index to treatment and as such makes a very adequate quick reference volume.

Disturbance of the Blood Coagulation in Infants*

THE well-known Swiss pediatrician, Fanconi, reports and discusses the carefully taken history of 47 infants suffering from various disturbances of the blood coagulation mechanism. Coagulation and bleeding time, prothrombin time, fibrinogen content, heparin content, calcium content, differential blood count, platelet count, etc., were determined by the most modern methods throughout the whole course of clinical observation. The cases are grouped under five main classifications: lack of fibrinogen, lack of calcium, lack of thrombokinase, hyperproduction of heparin, lack of vitamin K. The latter group is by far the largest. However, Fanconi emphasizes that most hemorrhagic diseases of the newborn are not caused by a single factor, but result from the interaction of various factors. Each time a new scientific discovery is made, its importance is overestimated. Thus, in consequence of the good results with vitamin K therapy, the K-avitaminose has been overrated as the sole cause of most hemorrhagic diseases in infants. An extensive bibliography increases the value of this small but very interesting book.

Ernst Fischer

Blood Disorders in Children†

WELL known, not only as a pediatrician, but also as an investigator, Dr. Kugelmass in this volume presents an authoritative and comprehensive discussion of a subject of importance, not only to the pediatrician, hematologist, and clinical pathologist, but also to the clinician at large.

The arrangement of the book follows the clinical rather than the hematologic viewpoint, and thus evaluates the blood picture in terms of the patient as a whole. A blood glossary and index of differential diagnosis based on both clinical picture and blood findings greatly enhance the usefulness of the book.

An outstanding contribution of great and general interest.

ITEM

The Laboratory of Mt. Sinai Hospital, Cleveland, Ohio, is making blood studies in suspected and known cases of trichinosis and shall appreciate it if readers of THE JOURNAL OF LABORATORY AND CLINICAL MEDICINE send whole clotted blood samples in such cases to Dr. B. S. Kline of that laboratory.

CLINICAL AND EXPERIMENTAL

THE HEART IN EXPERIMENTAL THYROTOXICOSIS*

Ernest D. Nora, M.D., and
Nathan Flaxman, M.D., Chicago, Ill.

THERE are three entirely opposite schools of thought concerning the effects of thyroid disease on the heart. One group is of the opinion that thyrotoxicosis has no effect on the heart except to increase the metabolic activity.[1] Another group is inclined toward the view that the thyrotoxic disease causes myocardial damage, hypertrophy of the heart, and various clinical cardiac manifestations.[2] A third group, championed by more recent work, is of the opinion that the thyrotoxicosis acts only as a catalytic agent and brings to the surface latent cardiovascular lesions.[3]

Opinions vary not only as to the specificity of the possible thyrotoxic cardiac changes, but also as to the probable cause of such alterations in the heart. Some hold the primary cause as the toxicosis, while others attribute any cardiac changes to an indirect cause, such as the increased heart rate. The third group, as mentioned, attributes any possible changes to previous heart disease, especially a rheumatic myocarditis.

Thyrotoxicosis, experimentally induced, has not been entirely successful in solving the problem of the cardiac lesions in hyperthyroidism. Specific lesions have been produced in various animals.[4] However, others have reported that they were unable to demonstrate specific lesions in the hearts of experimental animals.[5]

Neither the clinical nor the experimental data at hand are sufficient to enlighten the problem of the effects of the thyroid upon the heart muscle in hyperthyroidism. In an experimental study somewhat similarly performed, Menne et al.,[5] found certain cardiac changes in the hearts of rabbits that were

Received for publication, August 15, 1942.

fed desiccated thyroid, but they concluded that it was possible that similar changes might be produced by cardiac overwork irrespective of the presence of thyroxin in the circulating blood. In an effort to investigate further this important and complex problem, the following experiments were undertaken.

METHODS OF INVESTIGATION

The work was performed entirely on rabbits. The animals were all of average weight and age. They were housed in a warm room and fed a normal rabbit diet, sufficient in quantity to ensure normal maintenance in weight which was determined by periodic weighings every four or five days.

Electrocardiographic tracings with Lead II were taken to determine accurately the pulse rate. Needle contacts were not employed, but a method with Sanborn Redux Paste was used. The hair on the areas of the right foreleg and left hindleg needed for contact were shaved and the paste rubbed thereon. Eight strand copper wire electrodes were employed, and these were wound twice around the selected area on the limb and again covered with the paste. Being painless, the method did not excite the animals, and tracings were obtained rapidly.

A normal electrocardiogram was obtained from each animal after it had become accustomed to being tied down on the animal board. Tracings were taken about every seven days, or thereafter, or until the death of the animal.

They were divided into six experimental groups, as follows: Group I, rabbits in which only the cardiac inhibitory nerves were removed; Group II, rabbits in which the cardiac inhibitory nerves were removed and digifoline (Ciba) injected subcutaneously; Group III, rabbits in which the cardiac inhibition was removed and quinidine sulfate administered orally; Group IV, desiccated thyroid (Armour) fed rabbits; Group V, thyroid fed and digifoline injected rabbits; and Group VI, thyroid and quinidine fed rabbits.

In the first three groups, where the cardiac inhibitory nerves were removed, it was performed in the following manner. The animals were given ether anesthesia, and a midline incision in the neck exposed the carotid sheaths. The pressor nerve of the vagus was isolated on each side, and a 1 to 2 cm. section was removed. The carotid arteries were stripped of their coverings up as far as the bifurcation into the internal and external branches and then swabbed with absolute alcohol. The animals were allowed to recover in a warmed room for several days.

Animals of one litter were used in the last three groups to exclude, as well as possible, any previous cardiac changes. The animals were all housed and fed similarly, and, in addition, were fed desiccated thyroid to produce toxicosis. The amount of thyroid fed varied with each individual animal, some becoming toxic on 2-3 grains per day and others requiring as much as 8 to 16 grains per day. They were fed the thyroid until the symptoms of toxicosis were manifested by weakness, diarrhea, loss of weight, prostration, lethargy, and increased pulse. Some of the animals, those that survived, were then given a rest period, and when the pulse and weight returned to normal, a second toxicosis was induced. This was continued until the animal died, or a sixty-day observation period passed, when the animal was killed. Normal electrocardio-

graphic tracings were obtained as described, and tracings were taken every seven days thereafter.

Group I. Cardiac Inhibition Removed.—This group consisted of 11 rabbits that were operated in the manner described. Seven of the 11 animals died in one to seven days due to pulmonary complications, apparently resulting from the severing of other vagal branches besides the pressor nerve. Four animals survived and were killed at the end of the observation period. All were autopsied to exclude other conditions which might cause any cardiac pathology (Table I).

Although there were minor variations in certain cases, gross examination of the hearts in this group revealed that the muscle, in general, was moderately firm and the auricular chambers dilated. Epicardial fat was scant, and the ventricles appeared hypertrophic. The hearts of the seven animals found dead had dilated cavities filled with blood clots. The average weight of the hearts of the animals killed at the end of sixty days was 9.5 grams, and of those found dead, 9.4 grams. There was a difference in the thickness of the left ventricular musculature. In the animals killed it measured 7 mm. above and 5 mm. below, while in the animals found dead it was 5.7 mm. above and 4.3 mm. below. The length of the ventricles from the opening of the coronary artery to the tip of the apex was 3.1 cm. in the killed and 2.7 cm. in the animals found dead. The ventricular diameter was the same in both sets of rabbits, 1.6 cm.

For the microscopic examination three different sections were taken from all the hearts. One section was through the left ventricle, a second through the right ventricle, and the third section through a papillary muscle. In the animals that died shortly after operation no microscopic changes were noted in the heart muscle. In Rabbit No. 16, where the autopsy revealed a stitch abscess with penetration of the infection into the mediastinum and a resultant fibropurulent pericarditis, the microscopic examination of the heart showed hyalinization and separation of the muscle bundles with round and neutrophilic cellular exudation. In the four animals that survived the operation and were observed for sixty days, the findings were uniformly positive. These hearts showed hyalinization and granular degeneration with slight to moderate fragmentation and separation of the muscle bundles. Lymphocytic infiltration was noted in No. 3 and vacuole formation in No. 4 only.

Group II. Nerve Section and Digitalis.—The animals were operated on in the manner described and the pulse increase determined by the electrocardiogram. Ten days postoperative digifoline (Ciba, 2 c.c. equal 1 cat unit) injections were begun and each animal received two minims per pound of body weight daily. This was gradually increased until they received four to six minims per pound of body weight. Rabbit No. 14 had a pulse increase of 20 with the digitalis and died of over digitalization (Table II).

At the end of the sixty-day observation period, the three surviving animals were killed. Gross examination of the hearts revealed that the muscle was moderately firm, except in No. 14. Epicardial fat was scant or absent. The right heart chambers were dilated and the hearts appeared elongated. The heart weight averaged 7.7 grams. The ventricular length was 2.7 cm., the thickness of the left ventricle 6.5 mm. above and 5 mm. below, with a diameter of 1.6 cm.

P.O. is the postoperative rate.
A.D. is the rate after digitalis.

The general findings on microscopic examination included poor staining of the nuclei, moderate separation of the muscle bundles with hyalinization, marked granular degeneration and fibrosis. In No. 10, where the animal developed a localized abscess in the left thigh, the findings were especially marked with vacuole formation, granular degeneration and separation of the muscle fibers.

Group III. Nerve Section and Quinidine.—The animals were operated in the manner described. Fourteen days postoperative feedings of quinidine sulfate were begun. The first doses were gr. ss, which was increased to gr. i after two weeks' medication (Table III). In the four rabbits autopsied at the end of the observation period, gross examination of the hearts revealed a firm muscle, purple-gray in color, and scant epicardial fat. The average heart weight was 5.7 gm. The length was 2 cm.; with thickness of the left ventricle 4.5 mm. above and 3.5 mm. below, and a diameter of 1.6 cm. Microscopic examination revealed essentially a moderate degree of granular degeneration and vacuolization, with a slight degree of fibrosis and hyalinization, separation of the muscle bundles, and fragmentation of a moderate degree.

Group IV. Thyroid Feedings.—Toxicosis was produced in these animals by feedings of desiccated thyroid. All of the animals showed emaciation and cachexia. On gross examination (Table IV) the heart muscles were moderately firm and devoid of epicardial fat. The right heart chambers were dilated and the hearts appeared elongated. Grayish areas were prominent over the external surfaces of the left ventricles. The average weight was 4.3 grams, length 2.1 cm., thickness of the left ventricle 4.8 mm. above and 3.3 mm. below, with a diameter of 1.3 cm.

In the animals that died early due to toxicosis there were no histologic changes prominent on the microscopic examination. There were focal areas of early degeneration, hyalinization, and slight separation of the muscle fibers. In the other animals the changes were more marked. These showed areas of marked granular and fatty degeneration with a foamy appearance, marked separation of the muscle fibers with fraying and fragmentation, cullular infiltration, both round cell and neutrophilic, hyalinization and fibrosis of these areas.

Group V. Thyroid and Digitalis.—These rabbits were given the digifoline subcutaneously for four days prior to the time the desiccated thyroid feedings were begun. The feedings were continued until the symptoms and signs of toxicosis became evident; the digitalis was continued each day also. None survived the toxicosis; all showed evidence of severe emaciation (Table V). Gross examination revealed elongated hearts with the muscles purple-gray in color and moderately firm. The right chambers were dilated and filled with clots. Epicardial fat was very scant or absent. The average heart weight was 5 grams. The length of the left ventricle was 2.2 cm.; thickness, 4.2 mm. above and 3.3 mm. below, with a diameter of 1.42 cm.

Where the animals died within twelve to sixteen days, following eight to twelve days of thyroid feedings, the histologic changes in the heart muscle were not marked on microscopic examination. There were focal areas of hyalinization and moderate granular degeneration with fragmentation and

fraying of the muscle. Round and neutrophilic cellular infiltration were noted in two of the animals. The rabbit, No. 46, that lived the longest, 18 days, showed the most marked degenerative changes, which were fatty and graular, with vacuolization, moderate fibrosis, and marked neutrophilic and endothelial cellular exudation.

Group VI. Thyroid and Quinidine.—These animals were first fed quinidine for four days before desiccated thyroid was given. Both were then fed until the symptoms and signs of toxicosis were manifested. All of the animals died during the first toxicosis (Table VI). Gross examination revealed elongated hearts with dilated right chambers and scant epicardial fat. The muscles were purple-red and firm. The average heart weight was 5.8 grams. Average length was 2.2 cm.; thickness, 5 mm. above and 2.1 mm. below; and the average ventricular diameter was 1.5 cm. Many marked histologic changes were noted on microscopic examination. These consisted of moderate to marked fraying and fragmentation of the muscles with hyaline and granular degeneration, and cellular infiltration of the round and neutrophilic types.

ANALYSIS OF EXPERIMENTAL DATA

Several interesting points were brought out in this experimental study. In Group I, where the operation for the removal of cardiac inhibitory nerves was performed on 11 rabbits, only four survived the observation period of sixty days. Here there was only the increased heart rate with increased work for the myocardium. Apparently the tachycardia alone caused an increase in the ventricular measurements of the animals that lived sixty days. In Group II, animals that had the nerve section performed and received digitalis ten days later, the picture was practically similar. The average heart weight was not as high as in the first group, the cardiac rate having decreased after the tenth postoperative day due to the digitalis. In Group III, where the nerves were removed and quinidine fed, no great deviation was noted in the anatomical findings.

Cardiac changes became more manifest in the last three groups that were fed desiccated thyroid. The average weight loss was about the same. There was no doubt as to the evidence of an increased metabolism accompanied by an increased respiratory rate and an accelerated heart action. The longer the animals lived with the toxicosis, the greater were the cardiac changes. The hearts appeared elongated, and the histologic changes were considerably greater than in those animals who received no thyroid feedings.

COMMENT

There are many factors to be considered in the effects of thyrotoxicosis on the heart. It is generally agreed that thyrotoxicosis produces general muscular weakness. It uses up glycogen reserves so that endurance is markedly lessened from the overactivity. The heart usually shares this decrease in glycogen reserve and suffers according to the extent and duration of the loss. Tachycardia is due mainly to the increase of thyroxin in the myocardium which causes the heart to beat more rapidly and more vigorously.[6] However, tachycardia alone is not sufficient to cause marked cardiac alteration. It may produce

some changes, such as fragmentation and degeneration of the muscle, depending on its duration. It is a factor, secondary to thyroxin.

There was a great variety and a marked degree of alterations in the heart muscle. Whether the compensating and neutralizing capacity of the neuro-endocrine system accounts for some of the variations can only be theorized at this time. The quantitative results were too variable for a direct ratio correlation. Even in the experimental animal, there is a different degree of tolerance to thyroid medication, and it is plausible that this is caused by a synergistic and antagonistic interrelation of other endocrine glands.

Experimentally, in rabbits, thyroid extract produces definite myocardial changes in varying amounts. These changes are not proportional to the alteration of the heart rate alone nor dependent on a previous demonstrable infection. Nor is the myocardial damage proportional to the increased rate of speed per second.[5] Even though the cardiac lesion in thyrotoxicosis may not be specific or constant, the myocardial damage encountered, however the mechanism, is primarily due to the effects of increased thyroid on the heart muscle itself.

SUMMARY

Experimentally induced thyrotoxicosis in rabbits resulted in the following changes in the heart: parenchymatous and fatty degeneration, cellular invasion, fraying and fragmentation of the heart muscle, and fibrosis. Similar changes, but not as marked, were produced by cardiac overwork without an excess of thyroxin in the circulation. This was produced by cutting the depressor nerves and denuding the carotid sinuses of their investments in order to allow the heart to operate uncontrolled.

A heart that is induced to work more rapidly does respond with morbid anatomical changes, but these cardiac alterations are not as marked as those due to the summation of the effect of increased thyroxin on the myocardium and the tachycardia, which is again a thyroxin effect.

FATAL ANURIA FOLLOWING ADMINISTRATION OF SULFONAMIDES WITH REFERENCE TO TUBULAR NECROSIS AND REGENERATION*

JANE A. ERGANIAN, M.D., AND JOHN H. DOVAL, M.D.
ST. LOUIS, MO.

IN MOST reports on the effects of the sulfonamide drugs on the urinary tract, emphasis has been given to the deposition of crystals in the tubules of the kidney and the formation of concrements in the pelves and ureters. Less emphasis has been given to the direct toxic effect of these drugs on the renal epithelium. In experiments on the toxicity of sulfathiazole in mice, Rake, van Dyke, and Corwin[1] found only an occasional mouse in which there were advanced degenerative changes and necrosis in the epithelium of the proximal convoluted tubules. Similar observations are reported by Kolmer[2] in studies with sulfathiazole in rabbits. Tubular necrosis was found only in animals receiving the largest doses—0.2 Gm. per kilogram twice a day for ten days. Hellwig and Reed[3] emphasize the toxic effect of sulfadiazine on the convoluted tubules and distinguish between this effect and mechanical blocking of the tubules by crystals. The latter effect is stressed by Bradford and Shaffer,[4] who accent the need for early ureteral catheterization and pelvic lavage. Hellwig and Reed insist that lavage in their case was of no avail—that the lesion was one of toxicity instead of mechanical effect.

In a recent case studied at the St. Louis Children's Hospital the preponderance of clinical and pathologic evidence indicates that death from renal insufficiency was directly related to degenerative changes in the renal epithelium, and that the deposition of crystals in the kidney and pelvis was of minor importance.

CASE REPORT

G. S., a boy of nine months, was seen first in the Out-Patient Department on March 10, 1942, with acute rhinopharyngitis, bilateral catarrhal otitis media, and bronchitis. His temperature was 39° C. Sulfathiazole 0.25 Gm. every four hours (0.2 Gm. per kilogram), neo-

*From the Departments of Pathology and Pediatrics, Washington University School of Medicine, and the St. Louis Children's Hospital.

Received for publication, August 17, 1942.

synephrin nose drops, and an adequate fluid intake were prescribed. The temperature returned to normal within twenty-four hours, the infection cleared rapidly, and the sulfathiazole was discontinued on the fifth day. On this same day gross hematuria and sulfathiazole crystals in the urine were noticed, both of which disappeared within the next twenty-four hours. Three days later the temperature rose again to 39° C. because of recurrence of the otitis media. This time treatment was by bilateral myringotomy and sulfadiazine, 0.25 Gm. every four hours. The temperature again returned to normal within twenty-four hours, and the otitis media began to subside. No hematuria was noticed. On the fourth day of the relapse, vomiting occurred, and when the patient was hospitalized, examination revealed marked oliguria, considerable albuminuria, and 4 to 5 red blood cells per high-power field in a centrifuged specimen but no crystals of sulfadiazine. During the second twenty-four hours of hospitalization the temperature rose, only a few cubic centimeters of urine were voided, and generalized edema developed. The heart sounds were normal. Late the second day the kidneys were found to be enlarged and tender. On the third day the heart tones became poor, cyanosis and marked restlessness developed, and the child died fifty-four hours after hospital entry, despite administration of magnesium sulfate, oxygen, and sedation. Additional laboratory work included a negative Kline test; hemoglobin 11.3 Gm.; red blood cell count 4.5 million; white blood cell count 13,000; and Schilling differential of 6 per cent stabs, 55 per cent segmented, 37 per cent lymphocytes, and 2 per cent monocytes.

TABLE I

*As observed by the mother.

The autopsy (Washington University No. 9746) was performed two and one-half hours post mortem. The body was edematous; the face, especially about the eyes, was puffy due to subcutaneous edema. The serous cavities contained excessive amounts of clear yellow fluid without evidence of inflammatory lesions within them. The kidneys were similar; the right weighed 55 Gm. and the left 53 Gm. The capsules were tense, and during the process of section of the organs large amounts of reddish yellow fluid spurted around the cutting edge

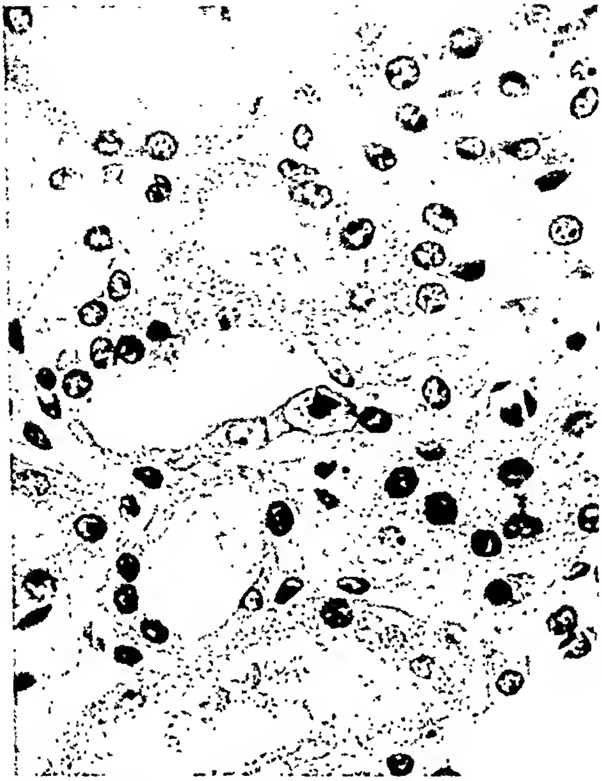

Fig. 1.—A mitotic figure is present in an epithelial cell in the center. In other tubules the cell membranes are indistinct and nuclei have disappeared.

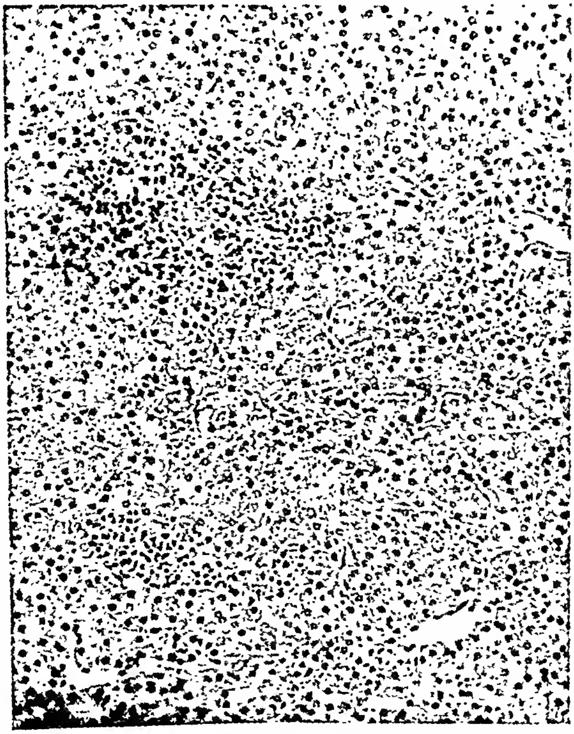

Fig. 2.—Focal necrosis in the liver. The hepatic cells are destroyed in these areas and there is an infiltration of leucocytes, lymphocytes, and a few monocytes.

of the knife. Approximately 10 c.c. of fluid were in the pelves and calices of these kidneys. The architecture of the organs was not unusual. There was a slight amount of dilatation of the calices and pelves. In the grayish white mucosa of the pelves were petechiae, and on the surface of the mucosa were many small yellow crystals. At the orifices of the ureteropelvic junctions were large aggregations of these crystals. These crystals were also found on the ureteral mucosa. The ureters were otherwise normal. The urinary bladder contained no urine. The remainer of the gross pathologic findings are listed below in the complete pathologic diagnosis.

Microscopic examination of the kidneys reveals moderate necrosis of the epithelium of the tubules, particularly of the proximal convoluted tubules. Within the lumen of the tubules are desquamated cells, eosinophilic debris, and occasionally red blood cells. Often there are syncytial masses of cytoplasm congregated at one end of a section of tubule with 4 to 8 well-preserved chromatic nuclei. Mitotic figures in the epithelial cells of the proximal tubules are moderately abundant (Fig. 1). Near the pelvic margins of the medullary papillae is noticeable dilatation of the tubules. Hemorrhage is present beneath the mucosa and within the adjacent tubules. The glomeruli are of moderate size, and the epithelial cells of the visceral layer of Bowman's capsule are cuboidal in shape, with deeply chromatic nuclei. Within Bowman's space there are a few desquamated necrotic cells and eosinophilic debris. There is slight interstitial edema of the cortex.

In the liver are many areas of focal necrosis (Fig. 2). These areas are small and contain necrotic liver cells, leucocytes, lymphocytes, and a few mononuclear cells. There is a moderate amount of cloudy swelling and fatty degeneration of the hepatic cells.

The complete pathologic diagnosis is as follows: Primary: Acute nephrosis with early regeneration of tubular epithelium; crystalline material in the pelves and ureters; hydronephrosis, bilateral; petechiae and ecchymoses of the mucosa of the pelves of the kidneys; edema of the subcutaneous tissues; ascites; hemorrhage of the middle lobe of the right lung; petechiae of the myocardium; hydrothorax, bilateral; focal atelectasis of the lungs; hyperplasia of the intrapulmonary lymphoid follicles; partially organized thrombi in the smaller branches of the pulmonary arteries. Accessory: Patent foramen ovale, guarded type, and immaturity of the kidneys.

COMMENT

The pathologic findings in the kidneys of this child indicate that there are two distinct lesions: one the result of crystallization of sulfathiazole in the ureters, pelves, and tubules; and the other, necrosis of the epithelium of the proximal convoluted tubules with early regeneration. It is not possible to attribute the anuria to either of these exclusively, but the preponderance of evidence indicates that the degenerative changes in the renal epithelium are more important. This conclusion is supported by the finding of regeneration, which might be expected to occur on the eighth to the tenth day following primary damage to the kidney, as in the case of poisoning with bichloride of mercury. In this patient the first sulfonamide was administered on March 10, and four days later there were gross hematuria and numerous crystals in the urine. Oliguria appeared on March 21, eleven days after the administration of sulfathiazole and three days after the first dose of sulfadiazine. It is improbable that the renal epithelium could have been damaged and could have showed beginning repair within the period of five days. It must then be concluded that the injury to the kidney resulted from the sulfathiazole given from March 10 to March 14, inclusive.

The sulfathiazole was given in therapeutic amount, and the reason for the damage to the kidney is not evident. It is possible that the mother did not give

the child an adequate amount of water, and that the concentration of the acetylated derivative in the urine was greater than in the usual case. There is also the possibility that the relative immaturity of the kidney may have played a role. The epithelium covering the visceral layer of Bowman's capsule was, in this nine-month-old child, still of the cuboidal type seen in newborn infants.

SUMMARY

1. A case of fatal anuria following the administration of therapeutic doses of sulfathiazole is reported.

2. An analysis of the pathologic findings indicates that injury to, and necrosis of, the renal epithelium were of greater physiologic importance than the usually emphasized formation of concrements and obstruction of the ureter and tubules.

CIRCULATION TIME: A REVIEW OF PREVIOUS METHODS AND THE INTRODUCTION OF AMINOPHYLLIN AS A NEW AGENT

Harry Koster, M.D., F.A.C.S., and Stanley J. Sarnoff, M.D.
Brooklyn, N. Y.

TECHNICAL difficulties have thus far interfered with direct measurements of the velocity of blood in the human being. An approximation has been suggested by the estimation of the "circulation time" which obviously varies inversely with the velocity. The estimations of circulation time are dependent upon the detection of the arrival at some previously chosen point of a substance introduced elsewhere.

The arrival of the substance may be detected by the patient, by the observer, or both. In general, it is expected that objectivity represents not only greater accuracy, but also wider applicability (children, uncooperative or comatose patients).

The earliest effort to measure circulation time was that of Hering[1] in 1827. Using the Prussian blue method he measured the time lapse between the injection of potassium ferrocyanide in one jugular and its appearance in the other.

From Crown Heights Hospital, Brooklyn.
Received for publication, Aug. 28, 1942.

In 1858 Vierordt[2] amplified and extended the use of this method and, after many experiments in different animals, predicted that in a human being with a heart rate of 72 per minute the circulation time from jugular to jugular would be 23.1 seconds.

In 1893 Stewart[3] injected methylene blue intravenously and detected its arrival elsewhere by transillumination. He also injected hypertonic sodium chloride solution, the presence of which was determined by the use of a galvanometer connected to nonpolarizable electrodes placed on a vessel. Meldolesi,[4] in 1925, and Koch,[5] in 1928, used the same method.

In 1922 Loevenhart[6] and his co-workers injected sodium cyanide intravenously and used a respiratory gasp as the end point at which time the cyanide was considered to have reached the carotid sinus. In 1933 Robb and Weiss[7] adapted this method for use in human beings. In normal subjects they found it to vary between 9 and 21 seconds, with an average of 15.6. The foot-to-carotid time averaged 27.7 seconds. This circulation time includes the time taken for the reaction to occur after the arrival of the cyanide at the carotid sinus. Olson, Levinson, Necheles, and Gutmann[8] in a study of circulation time in shock showed that the "reactivity time" of sodium cyanide varied constantly between 1 and 2 seconds.

In 1927 Blumgart and Yens[9, 10] devised a method for determining vein-to-artery and vein-to-heart time which made it possible to calculate the circulation time in the pulmonary circuit. They injected radium C into an antecubital vein and by means of a modified Wilson cloud chamber observed the time required to reach the heart and the opposite brachial artery, near the elbow. Blumgart and Weiss[11] found that the time from vein to artery varied from 12 to 24 seconds, with an average of 18 seconds. The pulmonary circuit time varied from 5 to 17 seconds, with an average of 10.8 seconds. This method undoubtedly is the most accurate one available, but its complexity makes its clinical use unfeasible.

Weiss, Robb, and Blumgart,[12] in 1929, found that the antecubital injection of histamine phosphate produced a flushing of the face upon the arrival of the histamine in the minute vessels. The arm-to-face time averaged 24 seconds. The method has been abandoned because of dyspnea, cardiac asthma, and headache as reaction phenomena.

Winternitz, Deutsch, and Brüll[13, 14] found that the injection of a solution of sodium dehydrocholate (decholin) produced a bitter taste upon arriving in the tongue capillaries. Tarr, Oppenheimer, and Sager[15] found the circulation time by this method to vary between 10 and 16 seconds.

In 1933 Fishberg, Hitzig, and King[16] used saccharin to measure the arm-to-tongue circulation time. A sweet taste signals the end point. The time by this method varies between 9 and 16 seconds.

In 1935 Teplov and Sor[17] used lobeline with a cough as the end point. They had from 30 to 40 per cent failures. The method was improved by Piccione and Boyd[18] who used a tickling sensation in the throat as an end point.

In 1935 Hitzig[19] used the injection of ether to measure the arm-to-lung circulation time. The detection of the ether in the expired air by the patient and often by the observer signals the end point. The lapse of time varies between 4 and 8 seconds.

In 1936 Goldberg[20] injected a solution of calcium gluconate and found that by using the sensation of heat on the tongue as an end point the arm-to-tougne circulation time averaged 12.4 seconds, varying between 10 and 16 seconds.

In 1936 Spier, Wright, and Saylor[21] injected a solution containing magnesium sulfate, calcium gluconate, sodium chloride, and copper sulfate. The arrival of the solution at various stations was signaled by a sensation of heat. They found the average circulation time of the arm to the tongue to be 14.6 seconds, to the hands 26 seconds, and to the feet 28 seconds.

In 1935 Zwillinger[22] suggested the use of magnesium sulfate as the test drug. In 1937 Neurath[23] employed this drug extensively, using the sensation of warmth in the head as the end point.

In 1939 Gubner, Schnur, and Crawford[24] used the inhalation of carbon dioxide to measure the circulation time from the pulmonary capillaries to the head. The end point was a feeling of warmth in the head and an acceleration and increased depth of respiration. This time ranged from 5 to 10 seconds.

In 1922 Koch[25] injected fluorescein to measure arm-to-arm time and found it to vary from 12 to 26 seconds.

Recently Fishbach[26] reported the arm-to-eye time estimated by the injection of sodium fluorescein to vary between 7 and 15.6 seconds. The end point is the appearance of a bright yellow fluorescence in the lower conjunctiva when viewed by ultraviolet light in a dark room.

A critical review of these methods strongly suggests the desirability of establishing criteria for the acceptance of any method. The most desirable method must conform to the following requirements:

1. The injected material must be nontoxic in the doses used.

2. The injection of a small quantity (1 c.c. or less) should be sufficient to give a sharp end point so that inaccuracies resulting from time loss during the injection be avoided.

3. The end point should be sharp and reliable.

4. The end point should be objective to eliminate the source of error inherent in the untrained observer and the possible sluggishness of mental reaction of the patient and to extend the applicability of the method to children, the uncooperative, and the comatose.

5. The minimum of apparatus in simple form is necessary to facilitate clinical use.

6. The agent used should be readily available.

The xanthines have long been known to be respiratory stimulants. The observation that the intravenous injection of one of them, aminophyllin, produced a sharp respiratory gasp suggested its use for the determination of arm-to-head circulation time.

METHOD

The patient should be lying flat on the back for the brief duration of the test. A No. 20 gauge needle is introduced into a vein in the antecubital fossa. The tourniquet is released and thirty seconds later 1 c.c. of aminophyllin (0.24 Gm.) is rapidly injected while a stop watch marks the moment of beginning of the injection. The awaited end point is a marked increase in the depth of inspiration which in many cases amounts to a gasp. While this occurs in every instance, in some it may be preceded by swallowing movements, a change in facial expression resulting from subjective sensations, or sharp catch during expiration. The first observable change is taken as the end point.

RESULTS AND DISCUSSION

Ninety-two patients at various stages in the postoperative state were subjected to this test. This included males and females ranging in age from 12 to 82 years.

The characteristic reaction of the patient was a transient dizziness, flushing, and a hyperpnea. In no case did this fail to pass off in a few minutes, and no other untoward effects were observed.

The circulation times varied from 7.1 to 20.4 seconds, averaging 12.4 seconds.

This test under the limited conditions of trial here described has been perfectly safe. No special apparatus is required.

The preparation is available in 2 c.c. ampules previously recommended for intramuscular use. Although as little as 0.25 c.c. is frequently sufficient to give an end point as determined by preliminary studies, the larger dose of 1 c.c. is preferable because it always gives the response, and yet it is still a small enough quantity to be quickly injectible.

Confirmation of the respiratory response to the intravenous injection of aminophyllin is found in the report of Sperling, Weisman, and Papermaster[27] who used it postoperatively in the hope of diminishing atelectasis and pneumonia. They graphically demonstrated the response by recording the respiratory excursion with the ordinary basal metabolism machine. In a study of twenty-two patients they found "an immediate increase of the depth of respiration averaging 51 per cent."

It is an objective method with a sharp end point. In the seventy-two instances in which it was used by us, in only one case was there any difficulty in recognizing the end point.

CHRONIC HEMOLYTIC ANEMIA WITH PAROXYSMAL NOCTURNAL HEMOGLOBINURIA*

Case Report With Experimental Studies

Byron J. Hoffman, M.D., and Roy R. Kracke, M.D.
Emory University, Ga.

CHRONIC hemolytic anemia with the accompanying features of hemoglobinemia and paroxysmal nocturnal hemoglobinuria is characterized by constant and excessive intravascular red blood cell destruction with exacerbations that are provoked by sleep, whether during the day or night. This syndrome was first described by Marchiafava and Nazari in 1911,[1] discussed again in 1928 and 1931 by Marchiafava,[2] and at length in 1931 by Micheli,[3] and is frequently called the Marchiafava-Micheli syndrome. Approximately 40 cases have been reported.

This disease has two fundamental features; first, the intravascular destruction of the erythrocytes, mainly during sleep, and secondly, the paroxysmal appearance of hemoglobin in the urine.

The agent producing this type of intravascular hemolysis remains unknown. The presence of hemoglobin in the blood plasma between the periods of hemoglobinuria, the anemia, if the regenerative efforts of the bone marrow do not fully compensate for the excessive hemolysis, and the persistent reticulocytosis are the signs of constant erythrocytic destruction. There is no familial tendency and no relation to food, drink, posture, drugs, or geographical distribution has been noted. Prolonged exposure to sun, severe chilling, and physical effort cause no exacerbations. About 70 per cent of the cases have been in males, with an average age incidence between 20 and 40 years. In the reported cases the disease has been fatal, usually within two to five years, and all therapeutic procedures, including splenectomy, have been unsuccessful. Mackenzie,[4] in discussing the "march" type of hemoglobinuria observed in soldiers after long marches, or occasionally in persons after severe physical effort, suggested that the increased blood levels of carbon dioxide during exercise may act as a hemolytic agent.

Ham,[5] who has studied this disease very thoroughly in five cases, concluded that the defect was present in the red blood cells, and not in the blood serum, and that the erythrocytes were abnormally sensitive, even within physiologic range, to normal variations of the blood pH toward the acid side during sleep. Ham, as well as Buell and Mettier,[6] demonstrated that the essential factor for hemolysis in the serum of these patients is destroyed by heating to 56° C. and is not restored by the addition of complement. Buell and Mettier,[6] after carrying out studies on the hydrogen-ion concentration, concluded that the fundamental disturbance appears to be in the red blood cells which become sensitized to a lysin normally present in human serum.

*From the Department of Pathology, Emory University School of Medicine, Emory University.

Received for publication, August 25, 1942.

In view of the above concept, alkali salts have been administered by various investigators in an effort to render the blood pH more alkaline, but this has resulted only in temporary improvement, followed by an increase in the degree of hemoglobinemia and hemoglobinuria. Likewise, in the case reported here, this has proved to be an unsatisfactory procedure, since the prolonged administration of alkali salts was followed by a marked accentuation of the hemoglobinemia and hemoglobinuria.

The mechanism responsible for hemoglobin in the urine includes two major factors. The first, as stated before, is the intravascular destruction of the erythrocytes in excess of the reticulo-endothelial capacity to convert the released oxyhemoglobin into bilirubin, thereby resulting in free hemoglobin being dissolved in the blood plasma; and secondly, the renal threshold for hemoglobin. The latter is based upon the functional capacity of the nephron unit to pass the large hemoglobin molecule when an adequate plasma concentration is attained. An explanation of this threshold might be found in Whipple's[7] "glomerular threshold" concept whereby it is assumed that hemoglobin passes through the glomerular filter and is rapidly reabsorbed by the tubular epithelium. As the rate of filtration through the glomeruli exceeds the rate of absorption by the tubules, hemoglobin appears in the urine. It is generally conceded that hemoglobin passes the glomerular filter. Bieter[8] has shown that the aglomerular nephron does not excrete hemoglobin even after being damaged with bichloride of mercury. As yet it is not known how the large hemoglobin molecule with a molecular weight of 67,800 passes the glomerular filter when the molecule of serum albumin with a smaller molecular weight of 67,000 fails to pass it. Bieter,[8] on the basis of variation in size of the glomerular membrane pores, has estimated that 3 per cent of these are of sufficient size for the passage of the hemoglobin molecule. Yet hemoglobin has been observed in the urine of these patients without albumin.

Factors other than molecular size may also be involved in the passage of proteins through the glomerular membrane. Risse[9] maintains that the electrical charge of the protein ion and the glomerular membrane is concerned. Webster[10] and his associates studied the physicochemical factors controlling the passage of proteins across the glomerular membrane and found that the elimination of dissolved hemoglobin by the perfused frog kidney was greatly increased at the acid side (pH 5.5) and was much less at the alkaline side (pH 7.8) of the pH range studied.

If the permeability of the glomerular membrane is altered on exposure to high concentrations of hemoglobin, albuminuria theoretically, at least, should accompany hemoglobinuria, yet it does not always do so. Different threshold values have been observed in human beings and in dogs. Monke and Yuile[11] have determined the average value for the initial rate of tubular absorption in dogs to be between 2 and 3 mg. per minute, with diminishing values to less than 1 mg. per minute after the threshold has been lowered by daily injections of hemoglobin sufficient to cause gross hemoglobinuria.

In summary then, the mechanism may be a combination of altered glomerular permeability and tubular reabsorption, but at the present time most of the evidence indicates that tubular reabsorption capacity is entirely responsible for the phenomenon and hemoglobin will appear in the urine when the plasma concentration attains a level of 130 to 150 mg. per 100 c.c.

CASE REPORT

Present Illness.—The patient dates the onset of his weakness from July, 1935, following the extraction of a tooth, at which time no unusual quantities of blood were lost. Because of this weakness he consulted a physician who informed him that he had pernicious anemia and advised treatment. Liver injections were begun. At about this same time he began to have indigestion which he described as a postprandial epigastric fullness, some abdominal gaseous distention, and a burning sensation which extended from the pharynx to the epigastrium. Some of his friends first commented on his pale appearance during 1934. After a vacation he returned to work in August, 1935, and continued his duties until hospital admission, except for an occasional day or two when he remained at home because of weakness. He was treated constantly by his physician with weekly injections of liver extract, and sometimes from two to three injections per week from 1935 until the first half of 1939. During 1935 he first noticed that his morning specimen of urine was frequently dark red to almost black in color. This continued to a variable degree until June, 1939, when the day urine specimens were sometimes dark and the morning specimen always red to black.

His anemia became so severe in 1938 that he was given his first transfusion. A total of six were given during this year and the first half of 1939. Each time he would return to his work after a few days of rest at home.

Following a transfusion he had a mild chill and noticed that his urine was much darker, but this was not disturbing for he had noticed the same type of discoloration on former occasions. Also, after another citrate transfusion of 500 c.c. of whole blood in November, a severe generalized urticaria and edema of the entire body occurred. These subsided following the administration of adrenalin subcutaneously, ephedrine sulfate by mouth, and several days of bed rest.

Past History.—Childhood illnesses included whooping cough and pneumonia at one year of age, and later mumps and measles without complications. During childhood he played with other children without fatigue. In 1928 he became employed in the box department of a paper company and remained at his job until May 1, 1935, when he was transferred to the stereotype department. This work was done in a poorly ventilated room and consisted of melting the metal composition at very high temperatures and pouring the type.

System Review: The cardiorespiratory, gastrointestinal, and genitourinary systems were negative except as mentioned above. There was no evidence of food allergy. He has never had areas of anesthesia, paresthesia, or hyperesthesia. There was a gradual loss of weight from 160 pounds in 1935 to 140 pounds in 1939.

Family History: His mother died in her late thirties following complications of tubal pregnancy; his father died at 50 years of age with Bright's disease; and one brother and one sister died in infancy from unknown causes. One brother is living and well. Deaths on both sides of the family have usually been due to kidney and heart disease.

Marital History: He married in April, 1935. His wife had always been in good health but never became pregnant as precautionary measures were taken.

Physical Examination.—He was a well developed and moderately well nourished white male, about 27 years of age, with a distinct pallor but no excessive skin pigmentation. His temperature was 98° F., pulse rate 88, respiration normal, and blood pressure 154/74. The positive physical findings were confined to a slight icterus of the sclera and a marked pallor of the conjunctiva and the oral mucous membrane. The gums around the lower central incisors were diseased with pyorrhea and were beginning to recede from the teeth. There was no evidence of cardiac enlargement. Soft blowing systolic murmurs were present at the mitral, aortic, and pulmonic areas. The aortic second sound was loud and snapping and greater than the pulmonic second sound. The liver was normal in size, the spleen was not palpable nor was its area of dullness increased. The reflexes were physiologic and lymphadenopathy was confined to a few small shotty glands in the inguinal region. The nail beds were very pale. The weight was 145 pounds.

Laboratory Findings.—

Erythrocytes	2,170,000 per cubic millimeter
Hemoglobin	7.7 Gm. (50 per cent)

Leucocytes	4,650 per cubic millimeter
Differential count	
Mature segmenters	54 per cent
Bands	14
Eosinophiles	1
Lymphocytes	25
Monocytes	6
Reticulocytes	20 per cent
Platelets	150,000 per cubic millimeter
Clot retraction time	Normal
Bleeding time	Normal
Coagulation time	Normal
Blood group	O (International)
Kahn	Negative
Volume index	1.01
Sedimentation rate	Westergren—70 mm. at one hour
	Wintrobe (corrected)—46 mm. at one hour

The stained smear revealed the erythrocytes to have an average or slightly larger than normal diameter, giving the appearance of slight macrocytosis with a slight degree of hyperchromia accompanied by a moderate variation in size and shape of the red blood cells. There were no abnormal leucocytes, and the platelets were normal in number and appearance. Thick- and thin-drop preparations for malarial parasites were negative. Blood examination during the night for filaria was negative. The van den Bergh reaction was indirect with 1.7 mg. of bilirubin per 100 c.c. of serum.

Icterus index	17	
Blood cultures	Anaerobic, aerobic, and under 10 per cent carbon dioxide were negative	
Blood chemistry		
Nonprotein nitrogen	32 mg. per 100 c.c.	
Creatinine	1.3 mg. per 100 c.c.	
Sugar (fasting)	106 mg. per 100 c.c.	
Calcium	11.6 mg. per 100 c.c.	
Phosphorus	3.6 mg. per 100 c.c.	
Chlorides (whole blood)	480 mg. per 100 c.c.	
Sodium (serum)	376 mg. per 100 c.c.	
Potassium (serum)	20 mg. per 100 c.c.	
Cholesterol	126 mg. per 100 c.c.	
Total protein	6.9 Gm.	
Albumin	4.0 Gm.	
Globulin	2.9 Gm.	
Fragility test	Control	Patient
Beginning hemolysis	42	42
Complete hemolysis	32	32

Spectroscopic examination of plasma and serum revealed absorption bands of oxyhemoglobin. No porphyrin or other abnormal bands were present.

Morning urine	
Color	Dark red
Specific gravity	1.025
Albumin	Trace
Acetone	Negative
Diacetic acid	Negative
Benzidine test	4 plus
Bile	Negative

Urobilinogen	Slightly increased. Morning specimen positive in 1:30 and day specimen 1:20 dilutions
Microscopic	Innumerable triple phosphate and amorphous phosphate crystals. No red cells
Spectroscopic	Revealed absorption bands of oxyhemoglobin. No prophyrin absorption bands were present

All specimens of urine voided during the day and night were saved. Without exception those voided during the night and on rising were red to black in color without the presence of red blood cells and gave a strongly positive benzidine reaction. The patient's sleeping habits were reversed so that he slept during the day and stayed up at night. Still the red to black urine followed sleep, whether during the day or night.

Donath-Landsteiner Chilling Test	Negative
Urine examination for lead	0.035 mg. per 100 c.c.—patient 0.035 mg. per 100 c.c.—control
Cevitamic acid content of urine per twenty-four hours	20 mg.

Cystoscopic examination and retrograde pyelograms were normal.

The kidneys excreted 67 per cent of the phenolsulfonphthalein dye in one hour after it was given.

Skin biopsy (stained with Prussian blue)	Negative for hemosiderin
Basal metabolic rate	Plus 8
Stool examination	There were no parasites, ova, or abnormal bacterial flora on culture studies.
Gastric analysis	
Fasting specimen	35 degrees free acid
30 minutes after Ewald meal	52 degrees free acid
Lactic acid	Negative
Blood and other abnormal contents	Negative

Skin tests for food sensitivity: Positive reactions were obtained for shrimp, scallop, crab, cherry, prune, cocoa, banana, carrots, celery, mushroom, cranberry, and dates.

Diagnosis.—The diagnosis of paroxysmal nocturnal hemoglobinuria was based on the nocturnal exacerbations of hemoglobinuria associated with the anemia, reticulocytosis, and hemoglobinemia. Paroxysmal cold hemoglobinuria, the most common of the paroxysmal types, was excluded since there was no history or clinical evidence of syphilis; the Wassermann, Kahn, and Donath-Landsteiner reactions were negative, and exacerbations of hemoglobinuria were not provoked by chilling.

Paroxysmal march hemoglobinuria was not considered, since it is usually observed in soldiers following long marches and is directly related in other isolated instances to physical effort. In the march type there is no evidence of a constant intravascular erythrocytic destruction, and even though there is a transient hemoglobinemia there is no sustained anemia, reticulocytosis, or icterus.

Favism,[12] a form of allergic paroxysmal hemoglobinuria, was excluded by the elimination without beneficial results of those foods to which the patient gave positive skin reactions.

EXPERIMENTAL STUDIES

Blood pH Determinations.—Procedure: Venous blood was drawn from the anterior cubital vein into a dry syringe without the use of a tourniquet. Heparin was used as the anticoagulant, and no suction was applied to the plunger of the syringe during the withdrawal of the blood. The Beckman glass electrode potentiometer was used to obtain the hydrogen-ion determination. After withdrawal the blood was immediately transferred to the cup of the instrument, the glass electrode was immersed, and the pH was determined. Controls were done on normal persons using the same instrument and technique. All blood specimens taken during waking hours were obtained after two or more hours of bed rest. Blood samples were taken immediately after being awakened in the morning, in the evening, and during the night hours (see Table I). The patient and control were awakened from sleep for the latter. In one instance the sleeping habits of the patient and control were reversed and determinations were made.

TABLE I

DATE	HOUR	pH OF VENOUS BLOOD		PATIENT'S PLASMA Hb.	COLOR OF PATIENT'S URINE	BENZIDINE REACTION OF URINE
		PATIENT	CONTROL	CONC. IN MG./100 C.C.*		
12/ 7/39	7:00 P.M. (up all day)	7:37	7:39	80	Yellow	-
12/ 7/39	12:00 P.M. (awakened from sleep)	7:40	7:43	180	Dark amber	+
12/ 8/39	7:00 P.M. (up all day)	7:29	7:32	110	Amber	-
12/ 9/39	7:30 A.M. (awakened)	7:33	7:30	280	Black	++++
12/10/39	12:00 P.M. (awakened)	7:43	7:24	270	Black	+++
12/11/39	7:00 P.M. (up all day)	7:43	7:32	120	Yellow	-
12/12/39	8:00 P.M. (up all day)	7:30	7:35	95	Yellow	-
12/13/39	8:00 A.M. (up all night)	7:39	7:35	105	Yellow	-
12/13/39	5:00 P.M. (slept during day)	7:39	7:31	185	Dark red	++
12/14/39	7: A.M. (up all night)	7:35	7:30	100	Yellow	-
12/14/39	1:30 P.M. (awakened from sleep)	7:45	7:42	181	Dark red	++

*Blood plasma of control contained no hemoglobin.

No consistent variations of the blood hydrogen-ion concentration, as indicated by blood pH determinations, could be shown on the specimen of blood taken after the patient was up the entire day or on the specimen obtained when the patient was awakened from sleep, whether during the night or at the usual

hour of rising. The mean average for pH determinations obtained after being awake was 7.35 and that after being asleep was 7.40; whereas that of the control subject during waking hours was 7.33 and after being asleep was 7.34.

The observations on this patient and the control showed very little difference in the pH of the blood after being awake and on being awakened from sleep. The mean values obtained after sleep are slightly more alkaline in both the patient and the control. In this case, there does not appear to be a definite relationship between the hydrogen-ion concentration of the plasma and the nocturnal exacerbations of the intravascular red blood cell destruction.

As Ham has pointed out,[5] it is possible that the deeper portions of the body have a greater variation of the blood pH, within the normal range, on the physiologic basis of a slowed blood stream and shallow respiration during sleep. However, it would appear that the slowed blood stream and shallow respirations during sleep are evidences of a lowered metabolism accompanying a decrease in the physiologic demands of the respiratory and circulatory systems at this time. Furthermore, the reserves of the blood buffer system should be adequate to compensate for slight variations of carbon dioxide during sleep without disturbances of the blood pH if it is capable of maintaining the balance during exercise.

Plasma Hemoglobin Determinations.—The blood plasma was utilized for quantitative plasma hemoglobin determinations by using the Sheard-Sanford photelometer. Comparatively large volumes of plasma (from 2 to 3 c.c.) were necessary to obtain accurate and consistent readings. A voided specimen of urine was obtained from the patient each time blood samples were drawn. The color and the benzidine reaction of each are recorded in Table I.

The plasma hemoglobin concentration obtained during different times of the day and night varied from 80 to 280 mg. per 100 c.c. of plasma. The lower levels occurred after being awake for a number of hours and the higher levels following sleep.

The urine specimens varied in color and intensity of the benzidine reaction. All the blood plasma concentrations between 80 and 120 mg. per 100 c.c. had an accompanying yellow or amber urine which did not contain hemoglobin, whereas the levels from 180 to 280 mg. per 100 c.c. had a urine red to black in color and a marked variation in the intensity of the benzidine reactions. No blood levels were obtained between 120 and 180 mg. per 100 c.c.

The urines were usually red and gave a 2 plus benzidine reaction when the plasma levels of hemoglobin were 180 mg. per 100 c.c. This would indicate, as near as can be determined from voided specimens, that the renal threshold for hemoglobin in this person is well below 180 mg. per 100 c.c., and above 120 mg. per 100 c.c.

Effect of Sympathetic Stimulant.—As sleep in this disease is accompanied by exacerbations of intravascular erythrocytic destruction, the physiologic features concerning the state of sleep were considered. The cause and nature of sleep remain obscure. Many theories have been advanced. Among the more widely accepted is that of Hess,[13, 14] who after extensive investigation concluded that sleep was a parasympathetic function. He pointed out in support of his theory that the constriction of the pupils, the bradycardia, and the vasodilatation

accompanying sleep are parasympathetic functions and respond to parasympathetic stimulants. On this basis, a series of experimental studies were carried out on this patient in an effort to determine the effects of sympathetic stimulants.

TABLE II

DATE	TIME AND AMOUNT DRUG GIVEN	URINE COLOR AND TIME VOIDED		COLOR OF SPECIMEN REMAINDER OF DAY	R.B.C.	HB. (GM.)	RETIC. (%)
1/25/40	None	Red 2:30 A.M. Benzidine positive	Black 8:00 A.M. Benzidine positive	Yellow to amber with occasional benzidine positive	2,100,000	7.8	18
1/26/40	0.5 c.c. adrenalin 9:00 P.M. and 1:00 A.M.	Light amber 1:00 A.M. Benzidine positive	Amber 7:00 A.M. Benzidine positive	Same	2,100,000	7.8	14
1/27/40	0.5 c.c. adrenalin 9:00 P.M. 2:00 A.M.	Yellow 2:00 A.M. Benzidine positive	Light red 7:00 A.M. Benzidine positive	Same	2,100,000	7.8	14
1/28/40 through 1/31/42	0.5 c.c. adrenalin 9:00 P.M. 2:00 A.M.	Dark amber 2:00 A.M. Benzidine positive	Amber 8:00 A.M. Benzidine positive	Same	2,260,000 2,240,000 2,470,000	8.3 8.5 8.5	12 12 14
2/ 1/40 2/ 2/40	Adrenalin omitted	Light red 4:00 A.M. Benzidine strongly positive	Light red 8:00 A.M. Benzidine strongly positive	Same	2,300,000	8.3	14
2/ 3/40 through 2/14/40	0.5 c.c. adrenalin 9:00 P.M. 2:00 A.M.	Yellow to amber 2:00 A.M. Occasional benzidine positive	Amber 8:00 A.M. Occasional positive benzidine	Same	2,250,000	8.6	14

The first was adrenalin. One-half cubic centimeter doses of adrenalin in oil (Parke, Davis & Co., 1:1,000 concentration) were administered subcutaneously at 9:00 P.M. and 3:00 A.M. each night (Table II). The date (Jan. 25, 1940) listed on Table II as having red to black urine after sleep is typical of the nocturnal hemoglobinuria occurring at that time. On the nights following the subcutaneous administration of adrenalin only an occasional urine contained sufficient hemoglobin to cause red discoloration. The injections were omitted on the nights Feb. 1, 1940, and Feb. 2, 1940, and the urines again were red with hemoglobin following sleep. The administration of adrenalin was resumed, and the urines returned to a yellow or amber color with only an occasional morning specimen having a positive benzidine reaction. The red blood cell count, hemoglobin, and degree of reticulocytosis were not appreciably altered during this time. The erythrocyte count increased about 400,000 cells per cubic millimeter and did not increase further even though the degree of nocturnal hemoglobinuria had decreased and the patient felt much better. The whole blood hemoglobin increased only slightly while the regenerative activity, as indicated by the degree of reticulocytosis, remained constant.

Synthetic suprarenin was then substituted for the aqueous extract of the suprarenal gland from Feb. 14, 1940, through Feb. 19, 1940. Beginning Feb. 16, 1942, the morning urines varied from a dark amber to very light red color, and all specimens after sleep gave a strongly positive benzidine reaction. During this period the red blood cell count remained at 2,300,000 cells per cubic millimeter.

All medication was discontinued on Feb. 19, 1940. After several days an occasional specimen voided during the night and the morning specimen of urine varied from a light to dark red color. Curiously enough, the synthetic suprarenin, in the same dosage and concentrations, did not bring about the same improvement in the hemoglobinuria as the aqueous extract of the medullary portion of the suprarenal gland. This would suggest the presence of additional beneficial agents in the natural extract other than adrenalin.

Effect of Parasympathetic Stimulants.—Since a sympathetic stimulant, adrenalin, had improved the state of hemoglobinuria and hemoglobinemia without appreciably altering the status of the blood, it seemed worth while to determine the effect, if any, of parasympathetic stimulants.

As an accentuation of the hemolysis and subsequent exacerbation of hemoglobinuria seemed possible, small doses of prostigmine (1 c.c. of a 1:4,000 solution) were given subcutaneously at the usual hours of 9:00 P.M. and 3:00 A.M. All urine specimens became normal in color, with only an occasional one giving a positive benzidine reaction. Injections of prostigmine were continued for seven nights. Then eserine sulfate in a dosage of 0.7 mg. subcutaneously at the same hours of 9:00 P.M. and 3:00 A.M. gave the same results. Pilocarpine hydrochloride in 3 mg. doses subcutaneously was started on March 11, 1940, and continued through March 26, 1940. All urines remained yellow to amber in color, free of hemoglobin, and the patient felt much better during this period of time. However, the red blood cell count never went above the level of 2,500,000 with 7.6 Gm. of hemoglobin. All urine specimens were of a normal color, with an occasional one giving a positive reaction for hemoglobin. Pilocarpine hydrochloride had been discontinued for twenty days before the urines voided during the night and on arising in the morning again became dark amber in color and consistently gave positive benzidine reactions. The red blood cell count at this time varied from 1,800,000 to 1,950,000, approximately 400,000 less than the levels obtained during the administration of parasympathetic stimulants.

Eschatin, the aqueous extract of the adrenal cortex prepared by Parke, Davis & Co., was started on April 15, 1940, in 0.5 c.c. doses subcutaneously at 9:00 P.M. and 3:00 A.M. and continued through April 25, 1942. This preparation was used because of the beneficial results obtained with the natural adrenalin, whereas the use of synthetically prepared epinephrine appeared to be of little or no value. The urines returned to a light amber or yellow color and were free of hemoglobin. After several days the red blood cell count increased to 2,300,000 cells per cubic millimeter but never attained higher levels.

Ten grams of sodium chloride were then administered orally in conjunction with the eschatin for a period of a week without beneficial or harmful effects. Then synthetic cortin, desoxycorticosterone, was substituted for eschatin during

a period of hemoglobinuria without alteration in the degree of the nocturnal hemoglobinuria.

The urines continued to be free of hemoglobin throughout the months of May and June, the erythrocyte count remained at about 2,200,000 cells per cubic millimeter, and the reticulocyte count varied from 10 to 20 per cent. At this time the patient was dismissed from the hospital, advised to limit his physical activities, and return for observation in the out-patient department.

Subsequent Course.—The patient did as he was advised and maintained an erythrocyte count of 2,100,000 with 21 per cent reticulocytes for the following six months. In January, 1941, he contracted influenza, and was hospitalized, and treated symptomatically. At that time the erythrocyte count was 1,680,000 per cubic millimeter with 12 per cent reticulocytes, but returned to 2,000,000 per cubic millimeter a few days after the infection disappeared. No hemoglobinuria occurred during this time. The temperature of the patient was always normal except during the upper respiratory infection. At this time the condition of the patient is about the same.

GENERAL DISCUSSION

The results of the agents employed in these studies are offered without an explanation of their mechanism. Papilian and Antonescu-Mazilu[15] recently investigated the antihemolytic action of adrenalin and showed that natural adrenalin inhibits the hemolytic effect of mercuric chloride and digitalis on erythrocytes in vitro and in animals. It is unusual that the aqueous extracts of the medullary and cortical portions of the adrenal gland will have similar effects on the nocturnal exacerbations of erythrocytic destruction. Yet the synthetic preparations of adrenalin and cortin were for the most part ineffective. This would suggest that the antihemolytic agent is neither adrenalin nor cortin, but another product which is present in both portions of the adrenal gland and is water soluble. Eschatin, the natural cortical extract, was more efficacious in decreasing the nocturnal exacerbations of hemolysis without having the stimulating side effects of adrenalin. Polycythemia[16] with characteristics of polycythemia vera has been observed in adrenal cortical tumors and basophilic adenomas of the pituitary.

The action of the parasympathetic stimulants is equally obscure. Stimulation of the parasympathetic system serves as an activator to the secretory epithelium of the gastrointestinal tract, its appendages, and the sweat glands of the integument. Perhaps the parasympathetic also serves to stimulate the adrenal gland to produce an antihemolytic agent or some product concerned with the development of erythrocytes that are more resistant to normal blood hemolysins.

These agents sufficiently decreased the hemolysis during the usual nocturnal exacerbations to lower the plasma hemoglobin below the renal threshold levels, thereby eliminating the symptom of hemoglobinuria which should be regarded as no more than a urinary manifestation of excessive intravascular red blood cell destruction.

It is not likely that the agents used in these studies acted favorably by altering the renal threshold for hemoglobin. Numerous physicochemical factors have been cited as controlling the passage of proteins across the glomerular membrane. Krogh[17] reviewed the evidence that the increased permeability of

the glomerular membrane often paralleled an increase in capillary diameter. Webster[10] and his associates, in their work on the perfusion of hemoglobin by the frog's kidney, found the glomerular membrane more permeable to hemoglobin and the capillary bed dilated at the acid end of the pH range. However, in the studies cited in this paper the hemoglobinuria was greatly lessened by capillary constrictors and disappeared with capillary dilators. Perhaps the improvement in the hemoglobinuria observed by Ham[5] following a limited administration of alkali salts and the relapse after excessive quantities results from an alteration in the physicochemical factors of the capillary bed of the glomeruli rather than the degree of intravascular red blood cell destruction.

It is impossible to know how much, if any, the course of the disease process has been altered in this patient by decreasing the nocturnal exacerbations of the hemolysis since the state of anemia has not been appreciably altered. Splenectomy has been reported to lessen the severity of the nocturnal hemoglobinuria, but the state of anemia and the downward course of the disease continued unaltered in these cases.

SUMMARY

1. A case of chronic hemolytic anemia with paroxysmal hemoglobinuria (Marchiafava-Micheli syndrome) is reported.

2. Reversal of the sleeping habits of the patient provoked hemoglobinuria during sleep, whether during day or night.

3. Determinations of the blood pH did not reveal abnormal variations in the hydrogen-ion concentration after the patient was awake all day or after sleeping all night. The mean average after sleep was slightly more alkaline (pH 7.4) than after being awake (pH 7.35).

4. The renal threshold for hemoglobin in this patient was between 120 and 180 mg. per 100 c.c.

5. The severity of nocturnal exacerbations of intravascular red blood cell destruction was markedly lessened by the use of adrenalin and eschatin, the aqueous extracts of the medullary and cortical portions of the suprarenal gland. Synthetic adrenalin and desoxycorticosterone did not alter the nocturnal exacerbations of hemoglobinuria.

6. The parasympathetic stimulants prostigmine, eserine sulfate, and pilocarpine hydrochloride were more efficacious than the suprarenal extracts in lessening the degree of the nocturnal red blood cell destruction and subsequent exacerbations of hemoglobinuria.

7. Pilocarpine hydrochloride was the most effective. On each occasion after its use hemoglobin disappeared from the urine for many days or even weeks.

8. The degree of anemia and reticulocytosis were not appreciably altered during the remissions of hemoglobinuria that were produced by the various agents employed in these experimental studies.

VARIATIONS IN SUSCEPTIBILITY TO CINCHOPHEN AS OBSERVED IN ANIMALS WITH BILE FISTULAS*

J. H. Annegers, M.S., F. E. Snapp, M.S., A. J. Atkinson, M.S., M.D., and A. C. Ivy, Ph.D., M.D., Chicago, Ill.

It has been suggested by clinical and experimental observers that in some instances, if not all, the toxic manifestations of cinchophen are due to hypersensitivity.[1]

In the course of our studies of the elimination of cinchophen in the bile of dogs with chronic biliary fistulas, observations have been made which show that some dogs are more sensitive than others and that some dogs react more markedly to the first dose of the drug than to subsequent doses.

In this study we have directed our attention to disturbances of cholic acid output in the bile as well as to such symptoms as anorexia, vomiting, and diarrhea. It should be stated in advance that the animals used in these experiments represent a selected group to establish variations in susceptibility in the same animal and in different animals with a bile fistula. The seven susceptible ani-

mals to be referred to come from a group of dogs with biliary fistulas which were given cinchophen several times over periods varying from two to thirty-three days.

METHODS

The animals had a chronic bile fistula of the Rous-McMaster type;[2] in addition, some had a duodenal fistula for the return of bile into the intestine. The animals weighed from 7 to 13 kg. All were allowed to recover from the operation and to reach a constant twenty-four-hour output of cholic acid on the standard diet. Numerous control tests on the diet with and without the return of bile had been conducted prior to the administration of cinchophen.

Three different types of experiments were performed. In those of Group I, the initial dose of cinchophen was given after a period of from three to four days, during which time the animal reached a basal control output of cholic acid on the diet fed twice daily without the return of bile. The cholic acid so formed comes from synthesis only. In those in Group II the daily ration of the standard diet was divided into three portions and fed every eight hours, with the bile secreted during the previous eight hours being returned to the duodenum during a period of about one hour after the meal. When the output of cholic acid had reached a relatively steady level, 0.333 Gm. of cinchophen was given with each meal. Thus the bile salts and cinchophen excreted in the bile (45 to 55 per cent of the oral dose) were subjected to three enterohepatic circulations daily. In the experiments in Group III, the animals, after being subjected to a basal control period on the diet without the return of bile, were given through the duodenal fistula the bile secreted during the preceding hour. At the start of the hourly return of bile, 0.5 Gm. of cinchophen was given with the meal, and another dose of 0.5 Gm. was given with the next meal twelve hours later, and thenceforth until 2 Gm. were given, the hourly return of bile being continued. Thus, the bile salts and cinchophen excreted in the bile were subjected to an enterohepatic circulation rather continuously as would occur in a patient without a gall bladder or with a nonfunctioning gall bladder.

The dose of cinchophen for the human adult varies from 2 to 5 Gm. daily, or from 30 to 70 mg. per kilogram. The average dose received by our animals was approximately 100 mg. per kilogram, or on the basis of body weight it was equivalent to twice the average dose given to man. A snow-white cinchophen powder* was used, which was odorless and completely soluble in alkaline aqueous solution.

RESULTS

Group I.—The four dogs referred to in Table I were allowed to reach their basal output of cholic acid on the diet. Then 0.5 Gm. of cinchophen was given with the meal every twelve hours for from three to five days.

One of the dogs B8, on the second day of medication (Table I) started and continued to vomit during the two-hour period preceding each meal. Since her stomach was about empty at the time, little food was lost. This is important because vomiting, particularly of food, decreases cholic acid output, since much

*Calco Chemical Co.

of the cholic acid is synthesized from the protein of the ingested food. After withdrawal of the cinchophen, the cholic acid output returned to the normal level within three days, during which time no vomiting occurred. Later, this animal was subjected several times to the same dose of cinchophen: no vomiting or anorexia and no decrease in cholic acid output occurred.

Table I

A Dose of 0.5 Gm. of Cinchophen Was Given With the Meals Twice Daily Without the Return of Bile

	2/6	240	1,620	0.5 Gm. cinchophen b.i.d.	
	2/7	234	1,640	0.5 Gm. cinchophen b.i.d.	
	2/8	249	1,620	0.5 Gm. cinchophen b.i.d.	
C7	Control	138	2,172	Control; average of three days unusually high output of cholic acid for control	
	2/5	262	1,892	0.5 Gm. cinchophen b.i.d.	
	2/6	203	1,386	0.5 Gm. cinchophen b.i.d.	
	2/7	227	1,118	0.5 Gm. cinchophen b.i.d.	
	2/8	336	1,688	0.5 Gm. cinchophen b.i.d.	
	2/9	326	1,923	0.5 Gm. cinchophen b.i.d.	
		The cinchophen was continued for twelve days with normal outputs of cholic acid, then withdrawn and started again three days later			
	2/20	276	488		
	2/21	311	928		
		The cinchophen was discontinued for two weeks and then it was given again for three days with the following results:			
	Control	181	2,280	Control period of 3 days	
	3/5	299	2,590	0.5 Gm. cinchophen b.i.d.	
	3/6	288	2,300	0.5 Gm. cinchophen b.i.d.	
	3/7	247	1,950	0.5 Gm. cinchophen b.i.d.	

Dog C7 (Table I) showed a similar depression of cholic acid output during the second and third days of cinchophen medication which returned to the "normal" level for this dog during the fifth day of medication. This animal manifested no anorexia or vomiting. The cinchophen was continued for a total of twelve days. Then the cinchophen after three days of withdrawal was resumed again. The cholic acid output markedly decreased, though there was no vomiting and no diarrhea. The drug was stopped for two weeks and then given for three days. Some, though not a significant, depression of the cholic acid output occurred on the third day. This dog represents a case in which the cinchophen caused a depression of cholic acid output each time it was given, more the second time it was given than the first. In addition, the cholic acid output was depressed without any apparent gastrointestinal symptoms.

Dogs C8 and C10 are included to illustrate that similar doses of cinchophen have no effect on appetite and cholic acid synthesis in some dogs.

Group II.—The animals in this group were fed every eight hours and received via the duodenal fistula after meals all the bile secreted during the previous eight hours, except 0.1 c.c. which was used for cholic acid determination. After the animals had reached a relatively steady state, 0.333 Gm. of cinchophen was given with each meal. The cinchophen excreted in the bile during eight hours after oral administration amounts to from 45 to 55 per cent of the oral dose. Consequently the liver of these dogs was exposed to about 1.5 Gm. of cinchophen each day. With the exception of the return of bile and the enterohepatic circulation of cinchophen, these experiments were analogous to those in Group I.

Dog C3 vomited the first day of cinchophen administration. After having received 1 Gm. of cinchophen, the medication was stopped, and then the bile return was stopped to ascertain whether the basal control output of cholic acid without the return of bile would be resumed. The data in Table II shows that although cinchophen caused vomiting, it had no definite effect on basal cholic acid synthesis on the diet, since the postcinchophen output of cholic acid was normal.

TABLE II

A DOSE OF 0.333 GM. OF CINCHOPHEN EVERY EIGHT HOURS WITH MEALS; THE BILE WAS RETURNED EVERY EIGHT HOURS JUST AFTER THE MEALS

DOG	DATE	BILE VOL. C.C.	TOTAL CHOLIC ACID (MG. PER 8 HR.)	REGIME
C3	Control	157	1,434	No bile returned, basal control
	8	218	5,002	Bile returned t.i.d.
	9	248	4,927	Bile returned t.i.d.
	10	353	6,332	Bile returned t.i.d., + 0.333 cinchophen; dog vomited once
	11	224	3,951	Bile returned first eight hours only
	12	251	1,475	No bile returned
C4	19	232	4,535	Bile returned t.i.d.
	20	246	5,511	Bile returned t.i.d.
	21	212	5,173	Bile returned t.i.d.
	23	268	2,847	Bile returned t.i.d., + 0.333 cinchophen; anorexia
	24	363	4,705	Bile returned t.i.d., + 0.333 cinchophen; anorexia
				(Other data omitted from Table. See text)
C2	8	212	5,856	Bile returned t.i.d.
	9	223	5,725	Bile returned t.i.d.
	10	365	7,895	Bile + 0.333 Gm. cinchophen t.i.d.
	11	340	6,557	Bile + 0.333 Gm. cinchophen t.i.d.
				(Other data omitted from Table. See text)

Dog C4 showed a significant (44 per cent) depression of cholic acid output during the first day of cinchophen administration. But on continued cinchophen administration, the output of cholic acid remained around 4.7 to 5.0 Gm. per day. The animal had a poor appetite but ingested the daily ration throughout, even during the first day when the output of cholic acid was depressed.

Dog C2 is included to illustrate an animal that showed no effect from the same dose of cinchophen.

Group III.—The animals in this test represent a group in which the bile was returned to the intestine hourly. 1. The animals were placed on the diet with

a meal every twelve hours without the return of bile (Column 1, Table III) until they reached a relatively steady output of cholic acid. 2. The bile secreted the previous hour was returned for a period of forty-eight hours, the cholic acid output for the forty-eight hours being determined by sampling the hourly specimens (Column 2, Table III). 3. Step 1, above, was repeated. 4. Step 2 was repeated except that 0.5 to 0.25 Gm. of cinchophen was given with each meal for forty-eight hours. 5. Step 1, above, was repeated.

TABLE III

A DOSE OF 0.25 OR 0.5 GM. OF CINCHOPHEN WAS GIVEN TWICE DAILY AND BILE WAS RETURNED HOURLY FOR FORTY-EIGHT HOURS; THE TOTAL CHOLIC ACID OUTPUT FOR SEVENTY-TWO HOURS IS GIVEN

DOG	TOTAL MG. CHOLIC ACID FOR 72 HOURS				REMARKS
	AVERAGE BEFORE TEST—NO BILE (24 HR.)	CONTROL TEST WITH BILE	CINCHOPHEN TEST WITH BILE	AFTER CINCOPHEN—NO BILE (24 HR.)	
A3	1,462	22,104	23,011	1,613	0.5 Gm. cinchophen b.i.d.
B3	1,547	--	9,109	910	0.5 Gm. cinchophen b.i.d.; dog died
D4	1,950	7,216	4,822	2,500	0.25 Gm. cinchophen b.i.d.
	1,630*	7,216	9,729	1,701	0.5 Gm. cinchophen b.i.d.; three weeks later
D6	1,023	8,577	5,731	1,252	0.5 Gm. cinchophen b.i.d.
	1,315*	8,577	8,997	950	0.25 Gm. cinchophen b.i.d.; two weeks later
	950*	8,577	7,416	1,060	0.5 Gm. cinchophen b.i.d.; three weeks later
D7	2,360	6,640	9,226	2,710	0.5 Gm. cinchophen b.i.d.

*These later tests are included to show the different cholic acid response to later doses of cinchophen.

Under the preceding plan the cinchophen excreted in the bile was subjected to repeated enterohepatic circulation. The dogs receiving 0.5 Gm. with each meal had their livers exposed to about 2 Gm. of cinchophen daily and the dog which received 0.25 Gm. with each meal had its liver exposed to about 1 Gm. daily. Thus it was possible to compare the effect of the cinchophen on bile formation when bile was being secreted at a rapid rate and the liver exposed to cinchophen constantly and to observe any after effects the cinchophen might have on basal cholic acid synthesis.

Dogs A3 and D7 were not affected by the cinchophen and are included to illustrate that some dogs show no ill effect from this dose and repeated enterohepatic circulation of cinchophen.

Dog B3, however, was markedly affected. It became sick during the second day and ate no food after the first day. The experiment was continued during the second day to ascertain if recovery would ensue. Cholic acid was completely depressed during the first twenty-four hours after cinchophen was stopped; that is, after four doses during forty-eight hours. After that, the cholic acid synthesis returned to about 50 per cent of the control level, in the presence of complete anorexia, and the animal died after having received only 2 Gm. of cinchophen. This animal died of some condition apparently caused by the cinchophen which was not significantly revealed by the mechanism re-

sponsible for cholic acid synthesis. Autopsy revealed only a severe gastroenteritis.

Dog D4 showed a 33 per cent depression of cholic acid output during the first period of administration of 0.5 Gm. cinchophen daily with return of bile and no depression of cholic acid synthesis after the cessation of cinchophen and the return of bile. However, at a subsequent period twice the dose of cinchophen had no apparent effect on the dog.

Dog D6 reacted like Dog D4 to the first period of administration of cinchophen and manifested no significant disturbance of cholic acid output during two subsequent periods, though a slight depression occurred with the second dose of 1 Gm. daily.

DISCUSSION

The variations in susceptibility of different animals to cinchophen has been observed by all who have used it for producing "peptic" ulcers in dogs and for studying its toxicity. We have observed the same variation in susceptibility in our dogs with bile fistulas.

We have also noted that the susceptibility is usually definitely less on the second and later administrations of the drug.

The symptoms in our dogs with bile fistulas were chiefly gastrointestinal (anorexia, vomiting, and diarrhea). This coincides with the observation made by Stalker, Bollman, and Mann,[3] Reid and Ivy,[4] and others,[5] who also observed that on continuous daily administration for several weeks the gastrointestinal symptoms frequently subsided after the first or second week, indicating an increase in alimentary tolerance. Death occurs early in those in which the gastrointestinal disturbance does not subside. Clinically it has been recommended that administration of the drug should cease if gastric distress occurs.[5]

The disturbance in cholic acid output observed in the animals reported in this paper can be accounted for by a gastrointestinal irritation, except in one instance out of seven. Any disturbance of protein digestion and absorption, since all the evidence indicates that cholic acid is synthesized from protein cleavage products, would decrease cholic acid production. Hepatitis of sufficient grade to cause a complete suppression of cholic acid synthesis occurred in only one dog (B3) and then only for one day, the dog succumbing to a severe gastroenteritis. It is possible, however, for cinchophen to disturb materially some important function of the liver which is not reflected by the rate of cholic acid synthesis. But, it is noteworthy that the rate of secretion of cholic acid was not materially affected, as shown by the dogs in Table III, when the liver is secreting bile salts at a level close to its maximum capacity.

We were disappointed in not observing a more definite and unequivocal hepatic injury as indicated by a reduction in cholic acid output in the susceptible dogs. The failure to obtain such evidence of hepatic injury, however, is consonant with the failure to find evidence of microscopic damage of the liver of dogs except when very large doses of cinchophen are given. No one has obtained any evidence of liver damage in the dog or any other animal unless more than 100 mg. per kilogram body weight of cinchophen has been administered.[1, 3, 7] Even then the gastroenteritis is so pronounced that one could

argue that the hepatic damage is secondary to the gastroenteritis. The only exception to the foregoing interpretation was Dog 17 (Table I), in which cholic acid synthesis was depressed definitely during two of three periods of cinchophen administration in the absence of gastrointestinal symptoms. Since diarrhea and vomiting did not occur in this animal, it appears as if the cinchophen was responsible for the depression of cholic acid synthesis. It is worthy of note that in this animal the bile was not being returned to the intestine.

SUMMARY

Seven dogs with bile fistulas with a duodenal fistula for the return of bile to the intestine, which were especially susceptible to the gastrointestinal irritation of cinchophen, were given doses of the drug (approximately 100 mg. per kilogram of body weight) equal to or twice the average human dose. Only seven of sixteen dogs with bile fistulas manifested the symptoms of anorexia, vomiting, or diarrhea under the conditions of our experiment. The output of cholic acid was studied under three conditions: (1) when the drug might affect cholic acid synthesis from a standard diet alone; (2) when the drug might affect both cholic acid synthesis and bile salt secretion as a result of the drug and bile salt excreted in the bile being subjected to three enterohepatic circuits daily; and (3) when the liver was continuously exposed to the cinchophen excreted in the bile by the hourly return of the bile. It was found that any changes in cholic acid synthesis and secretion observed in these susceptible dogs could be accounted for by the gastrointestinal irritation caused by the drug with but one exception. On repeated exposure of the dogs to the drug the gastrointestinal tract became more tolerant, and cholic acid synthesis and secretion were not disturbed.

The observations on the effect of cinchophen on cholic acid synthesis and secretion are consonant with the failure of others to find evidence of microscopic injury of the liver when similar doses of the drug were administered to dogs.[3] However, the one exception referred to shows that the drug may occasionally act on the liver to decrease cholic acid synthesis in the absence of objective symptoms of gastrointestinal irritation.

RELATION BETWEEN AMOUNTS OF PERTUSSIS ANTIGEN INJECTED AND PRODUCTION OF AGGLUTININS

John A. Toomey, M.D., William S. Takacs, B.S., Roy Averill, M.D., and Norman Lewis, M.D., Cleveland, Ohio

I

The freshly isolated disease-producing *Hemophilus pertussis* organisms called by us phase A[1, 2] and phase I by Leslie and Gardner[3] are used in active immunization in man. Although phase B organisms, termed by us the "nondisease-producing" stage (the "resting stage," the "fixed" bacilli, and phase IV by Leslie and Gardner), descend from the phase A types, they are said to be worthless as immunization agents. Guinea pigs can be protected against lethal doses of phase B organisms by the previous injection of phase B vaccine, but no protection is established against phase A organisms by actively immunizing these animals with phase A vaccines. Doses of the standardized phase B antigen (4 mg. of wet weighed organisms to 1 c.c.) used in previous experiments failed to produce any agglutinins against phase A bacilli.

The relative size of organisms in the two phase conditions is significant, the phase B type being 50 or even more times the size of phase A. One milligram of wet weighed phase A organisms contains definitely more bacteria than an equal amount of wet weighed phase B bacilli.

Years ago, Huenekens[4] stated that pertussis vaccines (phase B state) should be given in massive doses to secure results. Sauer[5] has recommended even larger doses of freshly isolated *H. pertussis* organisms (phase A state) for active immunization.

The size of the organism may conceivably be related to the ability to immunize and produce antibodies. Were the latter true, perhaps increased amounts of phase B organisms used as the stimulating antigen and injected into rabbits would produce a higher agglutinin titer in their blood serums against homologous and heterologous organisms than would smaller amounts.

From the Division of Contagious Diseases, City Hospital, and the Department of Pediatrics, Western Reserve University, Cleveland.
Received for publication, Aug. 31, 1942.

Methods and Materials.—No. 778 stock phase B strain culture (American Type Culture Collection) was grown in veal brain liquid medium.[6a] The viscid, sticky mass produced by the organisms was centrifuged down as much as possible, the supernate discarded, and the centrifugate dried and powdered in a lyophile apparatus. Some of the toxin previously described was nearly always present in this specimen.[6b] Twenty milligrams of the powder were added to each 1 c.c. of normal saline. Part of this 20 mg. suspension was diluted to make a standardized suspension of 4 mg. in 1 c.c. of normal saline. Eight rabbits were injected, four with the dose standardized at 4 mg. and four at 20 mg. The injections were given intravenously the same day and in the same amounts as previously described.[1]

The animals were bled ten days after the last injection of antigen. The blood was put in the refrigerator overnight, and the next day the blood serum was separated off by centrifugation. Agglutination tests were then done with twelve strains of *H. pertussis* (phase B state) that had become acclimated to veal brain agar. The type of agglutinin response has been described previously.[1]

There was an obvious increase in agglutinin titer in the blood serums of the four animals that received the larger doses of phase B organisms in toxin. The titer of agglutinins present in these latter animals was not tested to its end point in all instances, although with the smaller dosages an end zone was obtained.

The phase B antigen-antibody serum agglutinated Walker strain 4 plus at 1:640 and had no reaction at 1:1280. The exact end point between 1:640 and 1:1280 was not determined, but it was not pertinent since our objective was simply to determine if larger amounts of the same antigen, in this instance phase B organisms, in a small amount of toxin would cause an increase in agglutinin titer. The blood serum agglutinin titers of strains Walker, Nos. 13 and 15, were at least twice as high as that obtained with the lesser amount of antigen; those of Betty, Brescan, Nos. 5, 8, 12, 28, and 778, were at least four times as high; that of No. 23, at least eight times as high; and that of No. 9, sixteen times as high.

The results were clear-cut, and it could be concluded that when five times the volume of *H. pertussis* phase B organisms "in toxin" was used as an antigen, a relatively higher titer of agglutinating antibodies was produced than with one-fifth the volume of phase B organisms "in toxin."

The phase B serums were also tried with phase A organisms. The rabbit serums obtained by injecting 4 mg. of the antigen were consistently found wanting in agglutinin titer, as was found in a previous experiment where similar standardized doses of organisms were used as the antigen. The rabbit serum obtained by injecting 20 mg. of antigen showed suggestive plus-minus agglutination reactions in the 1:40 titer.

This might suggest the presence of specific agglutinins. However, although the phase A organisms used had all the qualities and characteristics of a phase A bacillus and had been carried on human blood potato agar, definite conclusions could not be reached, since all but one of these phase A organisms had been isolated several months before the experiment was done

and some of their phase A quality might have been converted into phase B quality, thus changing their reacting ability to specific serum. Especially was this suggestive since the one phase A organism isolated but twenty-six days prior to the experiment was not agglutinated in any dilution by phase B, 4 mg. or 20 mg. serums. Although phase B 20 mg. serums had been found to possess higher agglutinin titers than did phase B 4 mg. serums, it was still not known whether more antigen could produce a higher titer in the absence of what might be an enhancing "toxin."

This experiment with the dried antigen and toxin was repeated; the serums obtained were agglutinated against eight freshly isolated organisms that had been carried in their phase A state and the same organisms which had been acclimated to and grown on veal brain agar to a phase B state. The results were similar.

II

In the previous experiment, phase B organism antigen contained a "toxin" not present in the ordinary commercial vaccines. It was decided in so far as possible to work with pure organism antigens.

A relatively small amount of standardized phase A and B organisms had been used to inject the rabbit to produce agglutinins in the blood serums.

If the agglutinin titer of the serum were dependent upon the number of organisms injected, and if this number were increased more than in the last experiment and the "toxin" factor excluded, with the exception of that contained in the water of condensation, it might be that there would not only be an increase in blood serum agglutinin titer against the homologous phase B, but also against the heterologous phase A organisms.

Methods and Materials.—In the previous experiments, the organisms were grown in liquid media and "toxin" was produced. In this experiment, No. 778 *H. pertussis* stock phase B strain was grown on solid media brain veal agar for two days and mass production of "toxin" avoided. The growth was scraped off, wet weighed, and standardized at 4 mg. per cubic centimeter, 20 mg. per cubic centimeter, and 45 mg. per cubic centimeter. Two-tenths per cent formalin was added to the various standardized organism suspensions. The latter were shaken every day and kept in the refrigerator for seven days. Several rabbits weighing between 1 and 1½ pounds were bled and their serums tested for the presence of normal agglutinins, since occasionally agglutinins against *H. pertussis* are found in normal rabbits. When six animals had been obtained, the blood serums of which lacked normal agglutinins against either phase A or B organisms, two each were injected intravenously every four days with a different one of the three standardized suspensions, the dosages being 0.2 c.c., 0.5 c.c., 0.8 c.c., 1.2 c.c., 1.5 c.c., 1.8 c.c., 2.0 c.c., and 2.3 c.c. The rabbits were bled ten days after the last injection. The blood was left in the refrigerator overnight to allow clotting and was centrifuged the next morning until the serum was clear; it was then inactivated one hour at 56° C., and merthiolate preservative was added. Agglutination tests were done against homologous phase B and heterologous phase A organisms. There were three bleedings, on the thirty-second, forty-sixth, and sixtieth days after the last injection.

It was easy to inject rabbits intravenously with 4 mg. per cubic centimeter and 20 mg. per cubic centimeter of a standardized suspension of organisms, but difficulties were encountered with the 45 mg. per cubic centimeter dose. One of the rabbits (No. 149) injected with the latter amount died after the second dose of the antigen. One of the two animals substituted died after the first injection. Several other normal rabbits lacking agglutinins against phase A or phase B *H. pertussis* organisms were given the 45 mg. per cubic centimeter dose, so that even though the mortality rate might be high during the process of immunization, enough animals would remain alive at the end of the procedure to finish the experiment. Three of eight animals injected with the 45 mg. per cubic centimeter dose died during the course of injections.

Agglutination tests were set up against (1) twelve phase A organisms isolated and grown on human blood agar within a few months before the experiment was started and (2) six phase B organisms isolated several years prior and carried on veal brain agar. The first bleeding was done thirty-two days after the last antigen injection against many phase A organisms. There was an increase in agglutinins in the blood serums of three rabbits (Nos. 190, 120, and 147) injected with 45 mg. per cubic centimeter, and against a few phase A organisms in the serums of two others (Nos. 21 and 180). This ability to agglutinate had practically disappeared in the specimens of the second and third bleedings obtained forty-six and sixty-six days later. Thus, agglutinins against some phase A organisms can be produced by phase B bacilli, although to a titer of only 1:80. These agglutinins tend to disappear within a month or so after the last antigen injection.

These rabbits injected with 4 mg. per cubic centimeter or 45 mg. per cubic centimeter of phase B antigen showed good titer responses against their homologous phase B organisms in the first blood serums obtained. There might have been a slight increase in titer value with the 45 mg. per cubic centimeter antigen, but it was not too definite. There was an increase in the agglutinin titers against phase B organisms in the specimens of the second bleeding, which was about equal in all serums regardless of the amount of antigen stimulus, whether 4 mg. per cubic centimeter or 45 mg. per cubic centimeter. The agglutinin titers in the specimens of the third bleeding had decreased to approximately those of the first blood serums and were about the same no matter what the stimulus.

It could be concluded that there was an increase in agglutinins against phase A organisms found in the first blood serums of the animals injected with 45 mg. per cubic centimeter of phase B, a titer lost only sixteen days later; and there was a good and almost equal response to all phase B organisms, irrespective of the stimulating phase B antigen and the time of bleeding, the highest titer being found in the blood specimen withdrawn forty-six days after injection. This conclusion differs from that of Experiment I, but the previous results could be easily explained because of the differences in the stimulating antigen, since only organisms were used in this experiment, and in the former work the organisms were contained in toxin, which possibly enhanced their antigen effect.

III

Stimulation with more antigen made from phase B organisms did not seem to increase the titer production against phase B organisms. However, there did seem to be a slight increase against the heterologous phase A organisms, so that it was thought that the surviving animals of Experiment II should be stimulated further.

All five animals of Experiment II that had survived the dose of 45 mg. per cubic centimeter of the phase B antigen were injected weekly for ten weeks with 2 c.c. of phase B organisms standardized at 45 mg. per cubic centimeter. There was an eleven-day interval between the first injection in this series and the final bleeding of the last series. Two of the five animals died; each of the remaining three were bled three times—twelve, twenty-three, and forty-four days after the last injection.

Agglutination tests were done with the nine blood serums of the three animals against five phase A organisms (Nos. 1, 2, 6, 7, and 8) isolated several months previously, five phase A organisms (Nos. 3, 4, 5, 9, and 10) isolated within the previous month, and three phase B organisms. The titers of the blood serum against phase B organisms were as usual, while against some heterologous phase A organisms, they were at least 1:80.

In a collateral experiment, agglutination tests were done against three phase B organisms and ten organisms which had been carried on human blood agar for several years, organisms which were beginning to show some phase B qualities. The latter, though carried on blood agar, were agglutinated by rabbit blood serums, in most instances to a titer of at least 1:320, thus demonstrating some approach to a phase B state.

IV

It was difficult to secure enough freshly isolated organisms to start a simultaneous experiment with many organisms where all the experimental factors would be the same. Some organisms grow faster than others and, as in the last experiment, a month or more might elapse before an experiment can be started. Meanwhile, the organisms, although grown on blood, might be progressing to a phase B state so that the titer obtained by phase B organism antibody serum might represent a reaction against some B-ness which was beginning to appear with age in the phase A organisms. To settle this point, another set of experiments were done. This time organisms were isolated, grown a few times on human blood agar, frozen in a lyophile apparatus, and set aside until at least five strains had been collected. By this method, the phase A characteristics were neither altered nor lost, and the organisms remained in their originally isolated state. The method of procedure was the same as in Experiment III.

Here again it was demonstrated that the homologous phase B organisms can produce some agglutinins against the heterologous phase A bacilli. These reactions are noted in Chart 1. Of the three rabbits used, the agglutinin titers of the blood serums of Nos. 147 and 190 were the highest after the first bleeding, and those of rabbit No. 21 might have been considered the same or slightly higher after the second bleeding. No animal had much of an increase in phase A agglutinins after the third bleeding.

COMMENT

We still use the terms phase A and phase B and not phases I, II, III, and IV as do Leslie and Gardner.[3] This is not in agreement with Dozois, Flosdorf, and Kimball.[7] The latter, in their work, constructed certain artificial boundaries and attempted to demonstrate three phases of existence. Yet at the same time they presented data concerning certain strains in various of their phases, which, because they did not fall within the limits of their phase boundaries, were described as "unrepresentative" and atypical"—and this despite the fact that these very exceptions pointed to the existence of an imperceptibly graded transition between two extremes of statistical maxima and minima; namely,

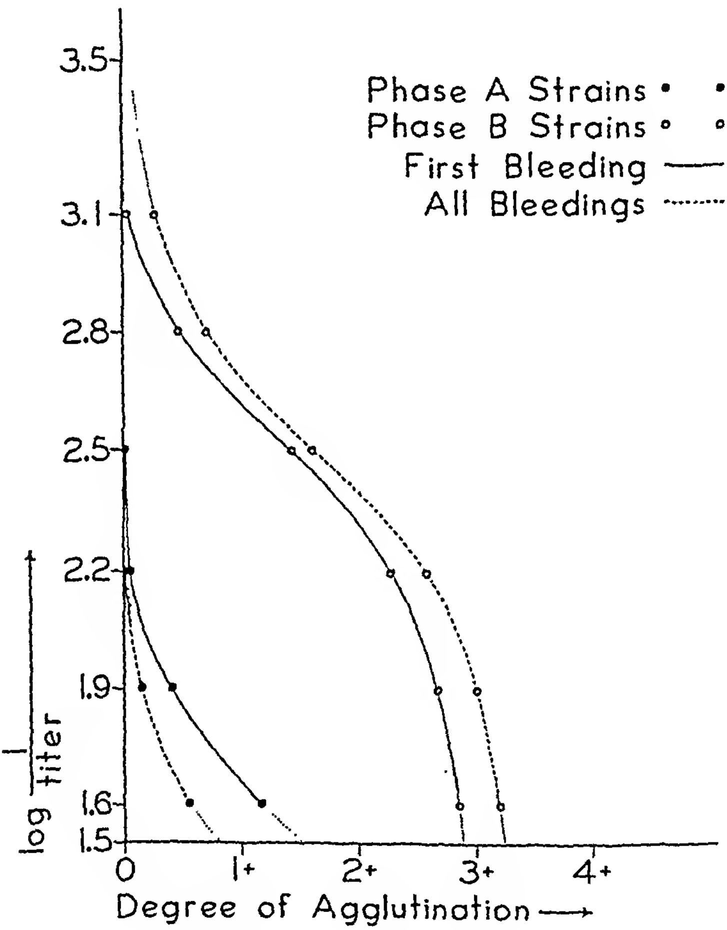

Chart 1.—Illustrating results of Experiment IV.

phases A and B (phase A, disease-producing stage; phase B, resting or non-disease-producing stage). Indeed, they explained away their "unrepresentative" strains by concluding that the phase relationships of *H. pertussis* are "more complex than was found by Leslie and Gardner," a conclusion with which we fully agree. In fact, the relationships are so complex that it would seem impractical to consider any other phases than the two previously mentioned.

Flosdorf and associates leave unexplained other data at variance with their theories, chiefly concerning the relationships between the cross-agglutination and cross-absorption characteristics of their phases I and III. They dismiss the fact "that the whole phase I organisms absorb phase III agglutinins" as "irrelevant, quantitatively, because other factors may be concerned in such reactions with particulate matter," a statement, which if true, should indicate that any agglutination or absorption test is subject to the same errors and is of proportionate relevance.

Flosdorf and associates did not agree with the premises on which we disputed Leslie and Gardner's assumptions as to phase existence. It has been shown, however, that *H. pertussis* organisms, if grown long enough on artificial media, with or without blood, gradually change their characteristics and in time reach a state in which all subcultured organisms, no matter what their original characteristics, acquire the ability to produce about the same degree of agglutinin titer in the blood serums of rabbits, have the same virulence, and appear morphologically the same as other phase B organisms carried on hemoglobin-free media. At the other extreme are the organisms freshly isolated from the human being ill with the disease, organisms which at the moment of isolation approach more or less the ideal opposite of the fixed stage. However, *H. pertussis* organisms seldom, if ever, attain either ideal extreme, for it has been shown here that by sufficiently intense programs of immunization it is actually possible to obtain cross-agglutinations between phases A and B. Would it not be theoretically possible to isolate any organism anywhere in its transition toward the resting stage at a time when it is losing some of the characteristics of phase I and acquiring some of the characteristics of phase IV and to immobolize it in this stage of its existence by a process of freezing and drying? This should not be impossible, since these authors themselves have demonstrated the existence of certainly more than four stages (phase variations).

It is our belief that the so-called phase II and phase III are only a few of the many possible "immobilizations of a phase" which might appear in the transition of organisms toward the resting or phase B state. The only two phases of which we ourselves are confident are (1) phase A, the disease-producing stage which in its freshly isolated state may have already started somewhat on its way toward the resting state and (2) phase B, the resting state.

Inferentially it could be said that if agglutinin production were a sina qua non of a good immunizing antigen, phase B organisms should be considered deficient as vaccines for human use.

SUMMARY

1. Rabbits given ten doses of phase B *H. pertussis* organisms standardized in toxin at 20 mg. per cubic centimeter have a higher agglutinin titer against phase B organisms than do the blood serums of those given the same number of doses of 4 mg. per cubic centimeter. Both antigens produced only a negligible titer of agglutinins against phase A organisms, the type which initiates the disease in man.

2. Four milligrams, 20 mg., and 45 mg. of phase B organims for ten injections will produce nearly comparable agglutinin titers in rabbits against phase B organisms and some demonstrable but not marked agglutinins against heterologous phase A bacilli.

3. When rabbits are injected weekly over a long period with massive amounts of phase B organisms as the antigen, there is no increase in titer against the phase B organisms, but in some instances there may be an increase in the agglutinin titer against phase A bacilli—as high as 1:160.

AN EXPERIMENTAL STUDY OF PHLEBITIS FOLLOWING VENOCLYSIS WITH GLUCOSE AND AMINO ACID SOLUTIONS

Abraham Horvitz, M.D., L. A. Sachar, M.D., and Robert Elman, M.D.,
St. Louis, Mo.

Although injury to veins during intravenous injections is of frequent clinical occurrence, often producing thrombosis sufficient to preclude further use of the vessel, there have been few experimental studies of the various factors which influence its degree and severity. Presumably these influencing factors are numerous, some of which are as follows: The character of the solution (its chemical properties, its pH, and its osmotic pressure), the size of the vein injected, the rate and duration of injection, the trauma produced in introducing the needle, the trauma produced by the needle while resting in the vein, stasis resulting from the partial occlusion of the vein by the needle, and the previous state of health of the vein.

The present study was undertaken primarily to determine whether the presence of amino acids, especially in solutions of glucose, influences the degree of injury produced by intravenous injections as compared with simple solu-

Received for publication, Sept. 3, 1942.

tions of glucose. As far as possible, all factors other than the character of the solution were kept constant.

METHOD

Dogs weighing approximately 10 kilograms were the experimental animals. The injections were carried out under nembutal anesthesia. Two pairs of veins were used: i.e., the large vein on the dorsum of both forelegs, known as the antebrachial cephalic, and the somewhat smaller, saphenous vein coursing along the inner aspect of both hind legs. The solution to be tested was administered on one side, the control solution simultaneously on the other side. Twenty-four hours later the two remaining veins were similarly injected. After a second twenty-four-hour period the dog was killed and the veins removed for section and study. Thus in most experiments each dog furnished two sets of veins, one showing changes twenty-four hours and one forty-eight hours after injection. The amount and rate of fluid injected were determined by the weight of the dog. Six cubic centimeters per kilogram per hour were accepted as fairly closely approximating the amounts used clinically. Because a three-hour injection usually produced definite changes with the first solutions used, this period was adopted. Twenty-gauge needles were used in all experiments, except in a few, which will be referred to below, when a twenty-five-gauge needle was used. The solutions were introduced at room temperature. The position of the point of the needle in the vein was marked by a silk suture placed in the skin just above it so that microscopic comparison could be made at the same distance from the point of injection. In early experiments sections were made longitudinally through the middle of the vein. In later experiments, cross-sections were taken two to three millimeters apart for use. The sections were stained with hematoxylin and eosin. In the study of many sections it was found that any injury observed was always greatest near the point where the end of the needle had rested. Thus, a section of vein taken about 1 cm. to either side of the needle point was used for the comparison.

Evaluation of Changes in the Veins.—In recording the changes in the veins, all observations were divided into those noted in the intima, those in the media, those in the adventitia, and also those within the lumen of the vessel. One of the earliest intimal changes observed in these sections was a vacuolation of the endothelial cells. This change might be observed in the absence of any other changes in the vessel wall. With further injury there occurred progressive cellular changes with ultimate death of the cells and destruction of the endothelial lining. Often, though not always, the denuded intima furnished a locus for the deposition of fibrin, and varying degrees of thrombus formation were observed. In the media the observed changes ranged from slight pyknosis of some of the nuclei to complete necrosis of the muscular wall. To establish a basis for comparing and evaluating the changes, they were classified as follows: (1) changes within the lumen, i.e., thrombosis: (2) changes in the intima, i.e., (a) endothelial vacuolation, (b) endothelial destruction: (3) changes in the media, i.e., (a) edema, (b) leucocytic infiltration, (c) hemorrhage, (d) necrotic changes; and (4) changes in the adventitia, i.e., (a) edema, (b) leucocytic infiltration, (c) hemorrhage. This classification is similar to though less detailed

TABLE I

EVALUATION OF THE SCORE INDICATING DEGREE OF DAMAGE TO VEIN DURING VENOCLYSIS

than that used by Ochsner and Garside[1] and by Ochsner and Mahorner[2] in their experiments on the effects of various sclerosing solutions used in the treatment of varicose veins. Each of the foregoing changes was recorded according to its severity. The absence of any change was rated as zero. Slight or early changes were rated as one, moderate changes as two, and advanced changes as three. By adding the ratings for each vein the final estimate or score of the severity of the phlebitis took the form of a total which was a rough numerical estimate of the degree of injury inflicted by the solution. While this type of scoring was based on the subjective evaluation of the degree of change seen, the observations were objective in so far as they were made with no knowledge as to which solution had been injected into the vein. When a number of the sections were rated separately by a second observer, the total scores obtained agreed rather well. A typical example of the method of scoring used is shown in Table I.

The amino acid solution tested in all experiments was made from an enzymatic hydrolysate of casein (Amigen*). The pH of this product in solution is approximately 4.5; when a more alkaline solution was tried, sodium hydroxide was added until the desired pH was reached. A 2.7 to 3.0 per cent concentration of the product in solution has been found to be isotonic with the blood; this is slightly greater than glucose. In comparing two solutions, each was isotonic.

FINDINGS

Eleven dogs were obtained for study, of which seven yielded four veins each, four but two veins each. In all, eighteen pairs of veins were observed. A summary of the scores is listed in Table II. The results are also described in detail as follows:

1. A 2½ per cent amigen solution in 10 per cent glucose was one of the first solutions tested against a control of 13 per cent glucose which has an osmotic pressure approximately equal to that of the amigen solution, as measured by its freezing point. In all three experiments (1, 1a, 2) no significant difference was found between the injury produced by the tested and the control solutions, although definite injury was produced in each case. The tendency to thrombus formation was frequent. When the injection of both test and control solutions was repeated twice in the same veins, thrombus formation and damage to the entire vein was marked. In all experiments injury produced by the same solutions was greater in the veins of the hind legs than in those of the forelegs. This was probably due to stasis because of the smaller caliber of the former; this factor is discussed below.

2. A solution containing 5 per cent amigen and 5 per cent glucose was tested against an 11.4 per cent glucose solution, the latter having an osmotic pressure equal to the former (Experiments 3 and 3a). In the forelegs the injury produced by the amino acid solution was greater than that caused by the glucose. In the veins of the hindlegs the damage produced by both solutions was severe, thrombosis being present in each case, and there was no significant difference between the two.

G., Glucose.
A., Amigen.

3. A solution containing 5 per cent amigen and 5 per cent glucose was tested against an isotonic amigen solution (8.8 per cent) and the score was even, i.e., in one experiment (Experiment 4) the former solution produced less damage, whereas in the other experiment (Experiment 4a) it produced more.

4. A 7.7 per cent amino acid solution, isotonic with a 10 per cent glucose solution, was tested against the latter (Experiments 5, 6, 6a). Thrombus formation was present in each case and the damage done to the vein wall was essentially the same for the two solutions in Experiments 6 and 6a, whereas in Experiment 5 the score for the amigen solution was eighteen against four for the glucose.

5. The significance of the pH of the amino acid solutions as a factor was also tested (Experiments 7, 7a, 8, and 9). In all experiments a 7.5 per cent solution neutralized to a pH of 7.4 produced less damage than the one left at pH 4.6; the difference was striking in three of the four experiments.

6. Early in these experiments, as noted above, it seemed trauma and stasis played an important part in the production of thrombosis. A small gauge needle, No. 25, was therefore tested against the larger standard 20-gauge needle. The same solution was, of course, injected through each needle at the same rate.

In one set of experiments (Experiments 10 and 10a) 2½ per cent amino acid in 10 per cent glucose was used. Here injury was greater in the veins injected with the larger (No. 20) gauge needle, this causing thrombus formation, whereas none was produced by the smaller (No. 25) needle. In the second pair of experiments (Experiments 11 and 11a) a 13 per cent glucose solution was used. No significant difference was found between the two needles. The different results obtained in these two sets of experiments may be due to a difference in the caliber of the veins of the dogs used.

COMMENT

Careful perusal of the scores listed in Tables II and III indicated the greater damage inflicted by the more hypertonic solutions, confirming many clinical observations. On the other hand, solutions containing 10 per cent glucose or less or its equivalent tend to produce less phlebitis. The presence of amino acids seems to have but slight effect on the amount of damage produced, although it is clear that the pH is an important factor. This probably explains the difference noted in Experiment 5, the only one in which there was a definitely increased phlebitis with amigen alone as compared with glucose alone. This effect is clearly demonstrated in Experiments 7, 7a, 8 and 9, in which the neutralized amigen provoked much less phlebitis than the unneutralized solution in all four sets of veins.

TABLE III

SUMMARY OF SCORES ATTAINED WITH DIFFERENT NEEDLES

EXPERIMENT	VEIN	NEEDLE	HOURS	SCORE	SOLUTION
10	R. F.	25	48	3	2½% Amigen
	L. F.	20	48	6	10% Glucose
10a	R. H.	20	24	17	2½% Amigen
	L. H.	25	24	4	10% Glucose
11	R. F.	20	24	13	13% Glucose
	L. F.	25	24	17	
11a	R. H.	20	48	26	13% Glucose
	L. H.	25	48	24	

The role of stasis and obstruction deserves some comment as already indicated. While a smaller needle should allow blood to flow around it, thus preventing stasis, this depends on the relative caliber of the lumen as compared with the gauge of the needle. It was our definite impression that this accounted for variations between the hind- and forelegs, although the objective evidence herein adduced does not permit such a conclusion. The considerations are of practical importance and deserve further study.

CONCLUSIONS

1. A method of scoring is proposed to measure the degree of phlebitis produced by intravenous injections.

2. Phlebitis is pronounced following a three-hour intravenous injection of a 2½ per cent amino acid-10 per cent glucose solution, due not to the presence of the amino acids but to the hypertonicity of the solution, inasmuch as the same changes are produced by isotonic (13 per cent) glucose solutions. Less

pronounced changes occur with more hypotonic solutions containing either amino acids or glucose or both.

3. Acid solutions tend to produce more phlebitis than neutral solutions as shown by comparing the damage produced by a 7.5 per cent solution of amigen at a pH of 4.6 with the same solution neutralized to pH 7.4.

4. The size of the needle used probably plays an important part in thrombus formation, although this factor is undoubtedly associated with the relative caliber of the veins.

ERYTHROCYTE LONGEVITY IN DOGS AND RABBITS*

JOHN EMERSON DAVIS, M.S., PH.D.
LITTLE ROCK, ARK.

NUMEROUS estimates have been made of the life duration of red blood corpuscles in various species. Ashby,[1] on the basis of agglutination experiments, has placed the life span of human transfused erythrocytes at thirty days or more. Eaton and Damren[2, 3] have studied the reticulocyte percentage peaks in rabbit blood following hemorrhage and have concluded that the life span of red cells in this species is about 8.5 days. Escobar and Baldwin[4] exposed animals to reduced atmospheric pressures to increase the number of red cells and then observed the time required for their return to normal at atmospheric pressure. This period of time was considered by the authors to represent the life duration of erythrocytes in the circulation. They thus obtained values of twelve to eighteen days in rats, sixteen to twenty-three days in dogs, and eighteen to thirty days in man. Hawkins and Whipple,[5] from a study of bile pigment output in dogs with biliary fistulas following hemorrhage or acetylphenylhydrazine, have reported that the life span of erythrocytes in this species is about 124 days.

The present communication presents a new approach to this subject through the depression of erythropoiesis by drugs in polycythemic animals. The experimental data for my calculations of erythrocyte longevity have been taken from previous papers[6-9] and other data of mine.

The method involves the production of experimental polycythemia in dogs or rabbits by daily exercise,[6] continued administration of cobalt chloride,[6-9] ex-

posure to low atmospheric pressure[7] or daily ephedrine administration.[9] The high erythrocyte counts were then reduced by the additional daily administration of raw liver, choline hydrochloride, mecholyl, or other vasodilator drugs. It has been found that only a few days are required for these substances to reduce the red cell counts to or toward normal to points which seem to represent the maximal depression that these drugs are capable of producing. It is assumed that these drugs act as a "brake" on erythrocyte production until the cell count reaches normal, or near normal. If such is the case, the rate of depression of the polycythemia should establish the rate of natural death of the erythrocytes, and it is then possible to calculate the length of time which would be required for 100 per cent disappearance of the cells if the process were to continue. This calculation has been made from composite or average curves drawn from rabbit and dog experiments.

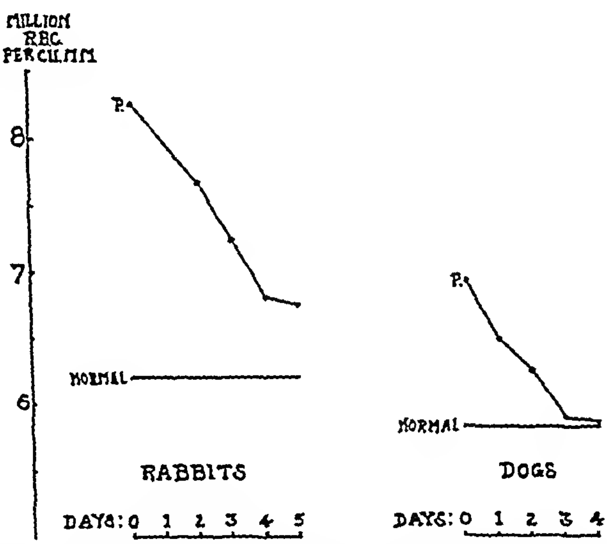

Fig. 1.—Average curves for rabbit and dog erythrocytes, showing the depression of experimental polycythemia by liver and various vasodilator drugs. *P* designates the average polycythemic level for each species.

RESULTS

Fig. 1 shows curves representing the depression by drugs of the average erythrocyte counts from polycythemic values to near normal in rabbits and dogs.

The average curve for rabbits is composed of twelve experiments on seven rabbits. It will be seen that four days were required for a practically maximal reduction of 17.8 per cent in the polycythemic cell count to occur. If this rate of reduction were to continue, all erythrocytes would disappear in 22.4 days.

The curve for dog erythrocytes represents thirty-three experiments on twenty dogs. It shows that a practically maximal reduction of 15 per cent of the polycythemic cell count occurred in three days. At this rate the last of the dog corpuscles would disappear in twenty days.

On the basis of these calculations, the minimal length of life of erythrocytes should be placed at twenty days in the dog and at about twenty-two days in the rabbit.

DISCUSSION

Our evidence for believing that the reductions of erythrocyte counts shown in Fig. 1 are due to a depression of erythropoiesis has been previously presented in articles cited above.[6-9] Since the depression occurs in spite of continuation of hemopoietic stimulating measures, and since the red cell count rises again to polycythemic values soon after cessation of administration of the depressant drugs, it seems justifiable to assume that the latter agents act as a "brake" on erythropoiesis. In some manner this brake seems to operate only until the erythrocyte number is reduced to a certain level which is not below the normal. We assume that the bone marrow still has an "excess momentum," so that when the "drug brake" is removed, an accelerated rate of hemopoiesis is able to cause a return of polycythemia in a few days.

Although it is recognized that the assumption that the rate of depression of polycythemia establishes the rate of natural death of erythrocytes is a broad one, it is perhaps permissible to say that it establishes the maximal rate of cell disappearance. Our calculated values for the life span of the erythrocyte should then be considered as minimum values.

CONCLUSIONS

On the basis of data on the rate of depression of experimental polycythemias by liver or vasodilator drugs, the *minimal average life duration* of erythrocytes has been calculated. The "life spans," thus obtained, are twenty days in the dog, and 22.4 days in the rabbit.

THE EFFECT OF CHANGE OF ALTITUDE ON THE BASAL METABOLISM OF HUMAN SUBJECTS*

ROBERT C. LEWIS, PH.D., ALBERTA ILIFF, PH.D., ANNA MARIE DUVAL, PH.D., DENVER, COLO., AND GLADYS M. KINSMAN,† PH.D., STILLWATER, OKLA.

IN A study of the basal metabolism of the children of the Child Research Council at Denver, sufficient data have been accumulated to establish normal values for different age groups from the third through the sixteenth year. That portion of the data obtained prior to April, 1936, for children between the ages of 2 and 13 years has been reported by Lewis, Kinsman, and Iliff.[1] Since the publication of this study, pediatricians and investigators in the field of energy metabolism have asked from time to time whether the normal values of basal metabolism thus established at an altitude of 5,280 feet can be used as standards at lower altitudes. In discussing this problem from the standpoint of the literature on the subject, the conclusion was drawn[1] that between barometric pressures of 610 and 645 mm. of mercury, at which the children were studied, the partial pressure of oxygen was not sufficiently low to influence their basal metabolism. However, in view of the queries raised as to the dependability of the standards of the Child Research Council at other altitudes, further consideration should be given to the question of whether the altitude at which determinations of basal metabolism are made affects the results.

Numerous investigators have studied the effect of altitude on the energy metabolism of human subjects. Observations[2-19] have been made by determining the oxygen consumption of the same individuals first at or near sea level and then at one or more higher elevations. It may be seen from Table I, which gives the percentage changes at different ranges of altitude from the heat production found near sea level, that considerable variation has occurred. However, no marked effect is evident in the case of altitudes below 10,000 feet. The greatest disagreement appears at the higher altitudes and is particularly noticeable in studies made prior to 1913 when the experimental conditions were not always well controlled. Since that time practically all of the observations have been made under basal conditions, and it may be noted that for altitudes between 10,000 and 15,000 feet the deviation from the results obtained at sea level has been considerably less than in the earlier years.

*From the Child Research Council and the Department of Biochemistry, University of Colorado School of Medicine, Denver, and the Oklahoma Agricultural Experiment Station, Stillwater.

This report is taken from the dissertation submitted by Alberta Iliff to the Faculty of the Graduate School of the University of Colorado, June, 1942, in partial fulfillment of the requirements for the degree Doctor of Philosophy.

A preliminary report of this study was made at the meetings of the American Society of Biological Chemists at New Orleans in March, 1940 (A. Iliff, G. M. Kinsman, A. M. Duval and R. C. Lewis, J. Biol. Chem. 133: xlvii, 1940).

Received for publication, Aug. 31, 1942.

†This author's participation in this study and its publication have been approved by the Oklahoma Agricultural Experiment Station.

Observations made during balloon ascents and in pneumatic chambers have also been used to study the effect of decreased barometric pressure on energy metabolism. The results of such experiments are not pertinent in relation to the problem under consideration, because the factor of acclimatization has entered into only a few of the investigations, and the purpose of the present study has been to determine whether altitude has a significant effect on the basal metabolism of acclimatized individuals.

Although this review of the literature reveals that change of altitude up to 10,000 feet has no significant effect on basal metabolism, the contrary conclusion has been drawn from a few studies[20, 21, 22] made at single elevations. In a later publication[23] the validity of such a conclusion will be questioned. However, inasmuch as these reports have appeared in the literature, the problem has been subjected to further investigation.

Experimental Procedure.—Although the primary purpose of this study was to determine whether the normal values of basal metabolism for children established at the altitude of Denver could be used as standards at lower altitudes, it was impracticable to use children as subjects of investigation. Accordingly, the study was made on seven adults. The basal metabolism of all seven subjects (two men and five women) was measured at Denver, Colo. (altitude, 5,280 feet) and at Stillwater, Okla. (altitude, 910 feet), and four of the sub-

jects (one man and three women) were also studied at Eldora, Colo. (altitude, 8,720 feet). During the period of residence at each place, no subject changed from that altitude by more than 1,000 feet for longer than one hour.

Three of the subjects (L., D., and I.) had been residents of Denver for at least ten years and had not been to an altitude lower than 5,000 feet for three months or longer before the first series of determinations was made at Denver. Between the completion of this initial period and the determinations in Stillwater, Subject L. spent four days at an altitude of about 900 feet but returned to Denver for 5 days just prior to leaving for Oklahoma. Subjects D. and I. remained in Denver until their departure for Stillwater. The other four subjects (N., K., H., and B.) had been residents in the Middle West for at least two years and had not been to an altitude higher than 1,000 feet during the three months before the first determinations were made on them in Stillwater.

After the initial period in Denver (Denver I), the three subjects, L., D., and I., motored to Stillwater on May 15 and 16 and remained there for twenty-four days. During their stay, basal metabolism determinations and blood studies were made on them and on the four residents of Stillwater. On June 10 the three subjects (L., D., and I.) returned to Denver where further determinations were made for a period of several weeks (Denver II). Subject H. came to Denver on July 1, and observations were made on her over a period of eight months while she remained at the higher altitude. On July 23 Subject K. arrived in Denver where determinations were made on her until August 5. These two latter subjects had remained in Oklahoma until their departure for Denver. In December, Subjects N. and B. came to Denver for determinations during a period of eleven days. They had been residing in Illinois at an altitude of about 700 feet since the end of the observations on them in Stillwater. Even though these studies on Subjects N., K., H., and B. constituted the first period of observations on them in Denver, this period has been designated, for the sake of clarity, as Denver II in the report to follow. Thus, for all seven subjects, the period known as Denver II indicates one following a change from a relatively low to a higher altitude.

Subjects D., I., and K. went to Eldora, Colo. on August 5 and were joined there by Subject L. on August 7. Determinations were made on all of them until August 21 when they returned to Denver where further observations were made in a final period at Denver (Denver III).

During the course of this study the living habits of the subjects were not materially changed at the different places. Indeed, the body weight and general physical condition of each subject varied little except for Subject L. who was ill just before the observations at Eldora. This illness occurred during a non-experimental period in Denver, and the weight of this subject remained relatively low throughout the period at Eldora and the final period at Denver.

The determinations of basal metabolism were made by the same individuals with the same closed circuit apparatus, a No. M 84 McKesson Metabolor, at all altitudes. From five to thirteen determinations were made on each subject in the initial periods, whether at Denver or at Stillwater. After each change in altitude, except during the third period in Denver, almost daily determinations were made for ten or more days. The subjects had fasted for at least twelve

hours and had rested on a comfortable bed in the laboratory for forty-five minutes before the first test to measure oxygen consumption was performed. In six instances only two tests were procured, since the variation in oxygen consumption from the mean was no greater than 2 per cent. In all other instances at least three tests of four minutes each or more were obtained. If the oxygen consumption of any one of the three tests showed a deviation of more than 4 per cent from the mean, another test was procured. When more than three tests were made, the deviation from the mean seldom exceeded 5 per cent. The mean value for oxygen consumption was used to calculate the heat production. As the respiratory quotient was not determined, 4.825 was used as the calorific value for each standard liter of oxygen. The basal metabolism calculated by the use of this factor is reported as calories per hour per square meter of body surface. The surface area values were obtained from a nomogram constructed by Wilson and Wilson[24] from the Du Bois and Du Bois height-weight formula.[25]

Eleven alcohol check determinations were made at intervals during the study, and these gave an average value of 0.4 per cent above the theoretical oxygen consumption with a range of from -1.5 to +2.9 per cent.

Blood studies made on each subject appear in a separate report by Lewis, Iliff, Duval, and Kinsman.[26] The values obtained for number of red cells, hemoglobin content, and packed red cell volume show that physiologic adjustment to altitude occurred comparatively early in the period of residence following each change in altitude.

EXPERIMENTAL RESULTS

The results of the individual determinations of basal metabolism are not presented here but may be found elsewhere.* For the most part, the values for each subject showed comparatively little variation in each period. However, it was found that on the first two days for Subjects L. and D. at Stillwater, on the first day for Subject I. at Stillwater, and on the first day for Subject H. at Denver the values for basal heat production (calories per hour per square meter) were markedly greater than those obtained subsequently during that period. Since these six high values were obtained in each case at the beginning of a period following a change in altitude and were distinctly out of line, they have been omitted in the calculation of the averages for the periods in which they occurred. However, even if these high results had been included, the means for these periods would not have been materially changed. Since in three instances the high initial values were observed on subjects who had moved from a higher to a lower altitude and in one case on a subject who had moved in the opposite direction, it is unlikely that the direction of change of altitude is the factor which caused these variations.

Table II shows the mean values for the calories per hour per square meter of body surface for the different periods as well as the standard errors of the means. From the latter values it may be observed that the means are reliable in all cases. Subjects N., I., K., H., and B show a close agreement in the means for the three altitudes. The values for Subject L. averaged 31.7 calories per

*The data of individual basal metabolism tests may be found in Part I, Table 2, of the ... hour per square meter in the initial period in Denver and from 34.0 to 34.4 calories in the four subsequent periods. The values for Subject D. averaged 34.4 calories per hour per square meter in the first period in Denver, but the subsequent means were all lower and varied between 32.0 and 33.1 calories. It should be noted that the changes after the initial period for Subjects L. and D. are in the reverse direction from one another.

TABLE III

SIGNIFICANCE OF THE DIFFERENCE BETWEEN MEANS OF BASAL METABOLISM FOR EACH SUBJECT AT DIFFERENT PERIODS AS INDICATED BY THE RATIO OF THE DIFFERENCE BETWEEN THE TWO MEANS IN EACH CASE TO THE STANDARD ERROR OF THE DIFFERENCE

DATA USED	$\frac{m_1 - m_2}{\sigma_D}$* FOR SUBJECTS						
	N. (♂)	L. (♂)	D. (♀)	I. (♀)	K. (♀)	H. (♀)	B. (♀)
Denver I and Stillwater		7.6†	4.5†	0.0			
Denver II and Stillwater	1.1	0.6	1.8	1.7	0.5	0.3	1.6
Denver III and Stillwater		0.7	0.8	0.5	2.6		
Denver I and Denver II		6.9†	3.2†	1.7			
Denver I and Denver III		3.7†	2.7	0.6			
Denver II and Denver III		0.4	0.4	0.6	2.7		
Denver I and Eldora		7.2†	2.0	0.8			
Denver II and Eldora		0.2	0.7	1.2	0.2		
Denver III and Eldora		0.3	0.8	0.0	2.2		
Stillwater and Eldora		0.9	2.0	0.8	0.7		

*The values used in the calculation of this formula are: m_1 = the mean obtained in one period, m_2 = the mean obtained in the other period, σ_D = the standard error of the difference or $\sqrt{\sigma^2_{m_1} + \sigma^2_{m_2}}$, where σ_{m_1} = the standard error of the mean of the values in one period and σ_{m_2} = the standard error of the mean of the values in the other period.

†The values so indicated are significant because the difference in the means is 3.0 or more times the standard error of the difference between the means.

Table III has been constructed to show whether there are any significant differences between the averages for the calories per hour per square meter of body surface obtained in the various experimental periods. The value given in each case is the ratio of the difference between two means to the respective standard error of this difference.[27] It may be seen that the differences between the basal heat production for any two periods are not significant for Subjects N., I., K., H., and B. On the other hand, the values for Subject L. show a significant difference between the initial period at Denver and each of the other periods. Similarly, the values for Subject D. indicate a significant difference between the basal heat production for the first period in Denver and those for the period in Stillwater and for the second period in Denver, respectively. However, when the comparison does not include the first period in Denver, it may be seen that the differences between the means of any other two periods for Subjects L. and D. are not significant. Since similar significant differences to those noted for Subjects L. and D. between the means of the initial period at Denver and those found at other altitudes are shown by these subjects between the means for the first period in Denver and for one or more subsequent periods at this same place, it is evident that factors other than altitude are responsible for the aberrant findings for these subjects in the initial period at Denver. Accordingly, it may be concluded that change in altitude up to 8,720 feet had no effect on the basal metabolism of any of the subjects studied.

In the present study lower values for intraindividual variability were found than those reported by Berkson and Boothby.[28] When the composite data for all periods on men and women, respectively, were treated by the procedure used by these authors on their similar data, the values for one standard deviation were found to be 1.27 calories per hour per square meter of body surface for the men and 1.19 calories for the women. Berkson and Boothby found 1.33 calories for men and 1.61 calories for women. Table IV, which gives the number of tests and the value for one standard deviation from the mean for each subject in each period as well as for the entire study, shows the greatest variability for any one period for the men to be 1.09 calories for Subject N. at Denver and for the women, 1.44 calories for Subject K. at Stillwater and for Subject D. at Eldora. Even when the calculation is made on all determinations of each subject, the highest values found are 1.30 calories on Subject L. for the men and 1.42 calories on Subject D. for the women. All of these values show a relatively low intraindividual variability.

TABLE IV

NUMBER OF TESTS AND VALUES FOR ONE STANDARD DEVIATION (σ)* FROM THE MEAN VALUE FOR CALORIES PER HOUR PER SQUARE METER OF BODY SURFACE OF EACH SUBJECT FOR EACH EXPERIMENTAL PERIOD

PERIOD	N. (♂)		L. (♂)		D. (♀)		I. (♀)		K. (♀)		H. (♀)		B. (♀)	
	NO. OF TESTS	σ	NO. OF TESTS	σ	NO. OF TESTS	σ	NO. OF TESTS	σ	NO. OF TESTS	σ	NO. OF TESTS	σ	NO. OF TESTS	σ
Denver I			10	0.82	10	1.35	10	1.18						
Stillwater	8	0.98	15	0.89	12	0.90	11	1.14	13	1.44	5	0.88	7	0.49
Denver II	10	1.09	10	0.65	17	1.08	13	0.73	7	0.74	15	1.25	11	0.73
Eldora			10	0.61	11	1.44	13	0.66	13	1.19				
Denver III			4	0.95	7	1.30	4	0.86	3	0.09				
All Tests	18	1.08	49	1.30	57	1.42	51	0.97	36	1.21	20	1.17	18	0.69

*The formula used for this calculation was that of Boothby, Berkson and Dunn[29] $\sigma = \sqrt{mS - M^2}$, where mS is the mean of the squares of the differences of the observed values from the mean value of the individual under consideration and M is the mean of these differences.

Although the primary purpose of this investigation was to determine the effect of altitude on basal metabolism, the nature of the study makes possible some observations on geographic location. Talbot, Wilson, and Worcester[30] believe that this is one of the factors which affects the basal heat production, and Talbot and Talbot[31] suggest that the principal reason for the disagreement between the standards of basal metabolism for children established by them in Boston and those reported for the children of the Child Research Council at Denver[1] is the difference in geographic location between the two cities. Boston is 2.8° farther north than Denver, and differences in latitude of this same order are found between the places at which the present study was made. Eldora and Denver are 3.0° and 2.6°, respectively, farther north than Stillwater. However, no evidence has been obtained in the present study which would indicate that differences in latitude of this magnitude cause significant differences in basal heat production. Thus, no confirmation can be given here to support the Talbots' contention that the disagreement between the standards of basal metabolism for children established by them in Boston

and by the studies of the Child Research Council in Denver is due to the difference in geographic location.

Whether the illness of Subject L. in Denver just prior to the experimental period in Eldora had any effect on the results obtained on him at the higher altitude might be questioned. However, the fact that the basal heat production in his case remained unchanged, just as it did in the other Subjects (D., I., and K.) who were also studied at Eldora, indicates that the illness had no significant effect.

In conclusion, it may be well to comment upon whether the question which prompted the present study has been answered; namely, whether the standards of basal metabolism established on children of the Child Research Council at Denver may be used at other altitudes. As has been explained earlier in this paper, practical considerations necessitated the use of adults as subjects in this investigation. However, there appears to be no valid reason for expecting a difference between the effect of altitude on children and on adults. Accordingly, since change of altitude did not affect the basal metabolism of the adults studied, the standards[1, 32] for the basal metabolism of children established at Denver may be considered reliable for use at altitudes below 9,000 feet.

SUMMARY

1. The basal metabolism of seven adults (five women and two men) was determined at Denver, Colo. (altitude, 5,280 feet) and at Stillwater, Okla. (altitude, 910 feet). Four of the subjects (three women and one man) were also studied at Eldora, Colo. (altitude, 8,720 feet).

2. The subjects remained at each altitude sufficiently long to become acclimatized as judged by certain observations made on the blood for the measurement of physiologic adaptation. During the period of adjustment to the changes in altitude, except after the return to Denver from a higher altitude, determinations of basal metabolism were made almost daily and also for some days after acclimatization had been accomplished.

3. Change in altitude within the limits of the elevations studied did not affect the basal metabolism.

4. Changes in geographic location within the limits and under the conditions experienced in this study had no effect on the basal metabolism.

5. A critical review of the literature shows that change in altitude at levels below 9,000 feet does not affect the basal metabolism and this view is confirmed by the present study. Thus, it may be concluded that for elevations below this level the standards[1, 32] for the basal metabolism of children established by the investigations of the Child Research Council at Denver are reliable.

THE EFFECT OF CHANGE OF ALTITUDE ON THE BLOOD OF HUMAN SUBJECTS*

ROBERT C. LEWIS, PH.D., ALBERTA ILIFF, PH.D., AND ANNA MARIE DUVAL, PH.D., DENVER, COLO., AND GLADYS M. KINSMAN,† PH.D., STILLWATER, OKLA.

IN CONJUNCTION with an investigation to determine the influence of altitude on the basal metabolism of adult human subjects, studies on their blood were conducted primarily as a means of ascertaining when physiologic adjustment to the changes in altitude occurred. These studies consisted of the determination of the number of red cells, the hemoglobin content, the packed red cell volume, and the specific gravity. Although it has often been observed that physiologic alterations in the blood occur with changes in altitude, seldom has such an opportunity as the one encountered in this study been afforded to observe the effects of altitude on the same individuals by identical techniques performed by the same workers and with almost no change in the living habits of the subjects.

EXPERIMENTAL PROCEDURE

The subjects of the study were five women and two men, and the altitudes at which the observations were made were 910 feet, 5,280 feet, and 8,720 feet above sea level. Only four of the subjects were studied at the highest altitude. The conditions under which the experiments were conducted are described in detail in our report on the effect of altitude on basal metabolism.[1]

Freely flowing blood was collected from the fingertip directly into small vials in which three drops of 0.5 per cent solution of heparin had been allowed to dry. The blood was usually drawn before breakfast, but occasionally it was taken at other times of day than early in the morning. By making a relatively deep puncture, it was possible to collect readily from six to ten drops (approximately 0.5 c.c.) of blood, and this gave adequate amounts for the determination of the number of red cells, the hemoglobin content, the packed red cell volume, and the specific gravity.

The red cell counts were made on at least two dilutions from each sample of blood. Hayem's solution was used in all cases. The pipettes and the Levy-Hausser counting chambers had been certified by the Bureau of Standards. More than 1,000 cells were counted from each pipette, and the mean value of the number of red cells per cubic millimeter for the two dilutions has been used.

---

*From the Child Research Council and the Department of Biochemistry, University of Colorado School of Medicine, Denver, and the Oklahoma Agricultural Experiment Station, Stillwater.

This report is taken from the dissertation submitted by Alberta Iliff to the Faculty of the Graduate School of the University of Colorado, June, 1942, in partial fulfillment of the requirements for the degree Doctor of Philosophy.

A preliminary report of this study was made at the meetings of the American Society of Biological Chemists at New Orleans in March, 1940 (Kinsman, G. M., A. M. Duval, A. Iliff and R. C. Lewis, J. Biol. Chem. 133: liii, 1940).

Received for publication, Aug. 31, 1942.

†This author's participation in this study and its publication have been approved by the Oklahoma Agricultural Experiment Station.

The hemoglobin content was determined by the acid hematin method. The Klett hemoglobinometer used for all readings was calibrated by comparison with the Van Slyke-Neill[2] manometer method of gas analysis for the determination of the oxygen-carrying capacity of the hemoglobin. In order to assure a constancy of light, the same daylight lamp was used at all altitudes, and a distance of 12 cm. from the light to the tubes was always maintained. Immediately after introducing the blood into the 0.1 N HCl, the solution was shaken for 3.75 minutes, and the readings were made within the following two minutes. This procedure had been found to give values very close to those obtained by the Van Slyke-Neill method when the conversion factor of 1.34 c.c. of oxygen for 1 Gm. of hemoglobin was employed. Two determinations that checked within 2 per cent were obtained on each sample of blood. The mean of these values has been used as the hemoglobin content of the blood.

The volume of packed red cells was determined by the use of Van Allen[3] hematocrit tubes. Instead of the clips or rubber bands customarily used to seal the lower end of the capillary tube, melted beeswax was employed for this purpose. The introduction of blood into the capillary tube was accomplished by drawing the blood up to the 100 per cent mark. After wiping the excess blood from the tip with a gauze sponge, the column of blood was carefully drawn up the capillary tube about ½ cm. Melted beeswax was then applied to the lower end of the tube with a camel hair brush and allowed to harden for three minutes. The tube was centrifuged at 2,500 revolutions per minute until there was no further change in the volume of the packed red cells. After centrifugation, the total volume of blood read at or very slightly below the 100 per cent mark, which showed that the air introduced into the lower end of the tube had escaped completely and that no blood had been lost. Triplicates from each sample of blood were run and usually the readings for packed red cell volume in all three tubes showed agreement. Unless two of the readings were within 2 per cent of one another, the determinations were repeated. The mean value for the two or three acceptable determinations has been used.

The specific gravity was determined by the use of the falling drop apparatus of Barbour and Hamilton,[4, 5] which was standardized by the use of solutions of potassium sulfate with specific gravities of 1.0551, 1.0645 and 1.0743. In the determination of the specific gravity, triplicate readings of the rate of fall of blood and of standard, respectively, were considered acceptable when they agreed within 3 per cent. The means of these values for the blood and for the standard were used in the calculation of the specific gravity of the blood.

In addition to the blood studies, measurements of pulse rate and blood pressure were made several times on each subject at each altitude. Since the results were normal in all cases and no significant variation occurred on changing altitude, the data will not be reported.

RESULTS AND DISCUSSION

Table I gives the results of determinations of number of red cells, hemoglobin content, packed red cell volume, and specific gravity on bloods collected in Denver at different times of day on Subjects D., I., and L. at a time when they were thoroughly acclimatized. It shows that in none of these determinations

is there a significant difference between the values obtained on fasting morning bloods and on those collected later during the day. Consequently, the few determinations that were made on blood collected under other than fasting conditions have been included in the data used.

Tables II, III, and IV give the means for the number of red cells, the hemoglobin content and the packed red cell volume, respectively, for the samples of blood taken at each altitude from each subject. In calculating these means, all values have been used except those obtained on the first three days after a change in altitude. The three-day interval was chosen arbitrarily, since the

changes observed in the different subjects showed no constancy with respect to the time of the beginning of the change or to its degree. In addition to the mean in each case, the tables give the standard error of the mean, the standard deviation from the mean, and the coefficient of variation. These statistical values show that there is relatively little scatter in the data obtained at any altitude for any of the subjects. When the means for each subject at the different altitudes are compared, it is seen that with an increase in altitude there were increases in eight instances for the number of red cells, in ten instances for the hemoglobin content, and in nine instances for the packed red cell volume out of eleven possibilities in each case. Thus, in the majority of instances adjustment to a higher altitude was manifested by increases in all three of these values.

Exceptions to the general rule that increases in the number of red cells, in the hemoglobin content, and in the packed red cell volume occur with an increase in altitude are to be found in some instances in the cases of Subjects H., K., and L. Practically no difference in the means occurred in any of these values when Subject H. moved from Stillwater (altitude, 910 feet) to Denver (altitude, 5,280 feet) or in the number of red cells or in the packed red cell volume when Subject K. went from Denver to Eldora (altitude, 8,720 feet). No reasons are evident for the inconsistencies found in these cases. When the mean values for Subject L. during the period at Eldora are compared with those obtained during the experimental periods in Denver, definite decreases in number of red cells and in packed red cell volume and practically no change in hemoglobin content are observed. An illness experienced by this subject during a nonexperimental period in Denver just prior to his departure for Eldora may

account for his failure to have attained higher means for the number of red cells, hemoglobin content, and packed red cell volume at the higher altitude. Four days before he went to the higher altitude, determinations on his blood showed that the number of red cells had fallen to 5.14 millions per cubic millimeter and that the hemoglobin content had dropped to 15.8 Gm. per 100 ml. of blood. Although recovery was rapid, as shown by the fact that six days later or two days after reaching the higher altitude the number of red cells had increased to 5.75 millions per cubic millimeter and the hemoglobin to 17.2 Gm. per 100 ml. of blood. the mean for these values and for packed red cell volume during the period at Eldora probably did not reach the height they would have attained, had this period not followed so closely upon his illness.

Table V gives the mean, the standard error and the standard deviation of the mean, and the coefficient of variation for the specific gravity of the blood at the different altitudes. For any given altitude very little intervariation or intravariation occurs. However, when one compares the mean of each subject at one altitude with that of the next higher altitude, it may be seen that in eight out of eleven possibilities slight but definite increases in specific gravity take place. Since the specific gravity of red blood cells is approximately 1.090 and that of serum 1.027,[6] each 5 per cent change in packed red cell volume would be expected to result in a parallel change of 0.003 in the specific gravity of the

	Eldora and Stillwater		0.1	1.1	2.4	1.1		

*The values used in the calculation of this formula are: m_1 = the mean obtained at the higher altitude, m_2 = the mean obtained at the lower altitude, σ_D = the standard error of the difference or $\sqrt{\sigma^2_{m_1} + \sigma^2_{m_2}}$, where σ_{m_1} = the standard error of the mean of the values at the higher altitude and σ_{m_2} = the standard error of the mean of the values at the lower altitude.

†The values so indicated are significant because the difference in the means is 3.0 or more times the standard error of the difference between the means.

whole blood. It is interesting to note that, except for Subjects D. and H. in changing from Stillwater to Denver and for Subject K. in going from Denver to Eldora, the alterations in specific gravity which do occur are in the direction and of the approximate magnitude to be expected from the changes in packed red cell volume shown in Table IV.

Table VI has been constructed to show whether the changes in the number of red cells, in the amount of hemoglobin, in the packed red cell volume, and in the specific gravity of the blood, which have been observed to occur with an increase in altitude, are significant. In eleven out of fifteen possibilities significant increases in the number of red cells and in the amount of hemoglobin occurred with an increase in altitude. Fewer marked changes were observed in packed red cell volume, for only three of the seven subjects showed significant increases with a change in residence from Stillwater to Denver, and only one of these showed a significant increase in changing from Denver to Eldora. No significant changes in specific gravity were found.

SUMMARY

1. Determinations of the number of red cells, the hemoglobin content, the packed red cell volume, and the specific gravity were made on the blood of seven adult subjects (five women and two men) at Stillwater, Okla. (altitude, 910 feet) and at Denver, Colo. (altitude, 5,280 feet). These same determinations were also made on the blood of one of the men and three of the women at Eldora, Colo. (altitude, 8,720 feet).

2. Although there was considerable variation in the amount of response of different individuals, and in a number of cases no significant change occurred, increases in the number of red cells, in the amount of hemoglobin, and in the packed red cell volume were found in the majority of instances with increases in altitude.

3. Definite but insignificant increases in specific gravity were found to occur in the majority of the cases with each increase in altitude. With few exceptions, these changes in specific gravity were in the direction and of the approximate magnitude to be expected from the alterations in packed red cell volume.

LABORATORY METHODS

GENERAL

AN ELECTRONIC DEVICE FOR THE LOCATION OF METALLIC FRAGMENTS IN VIVO*

CON FENNING, M.D., SALT LAKE CITY, UTAH

MOORHEAD has called attention to a foreign body finder.[1] I wish to call attention to a simple electronic device consisting of a minimum of parts which can be used in a similar manner. It is self-contained in a portable case, measuring 6 by 6 by 6 inches and weighing 8 pounds. The circuit to be described may be so adjusted that it has discriminatory powers which may be of use in applications other than the localization of in vivo foreign bodies.

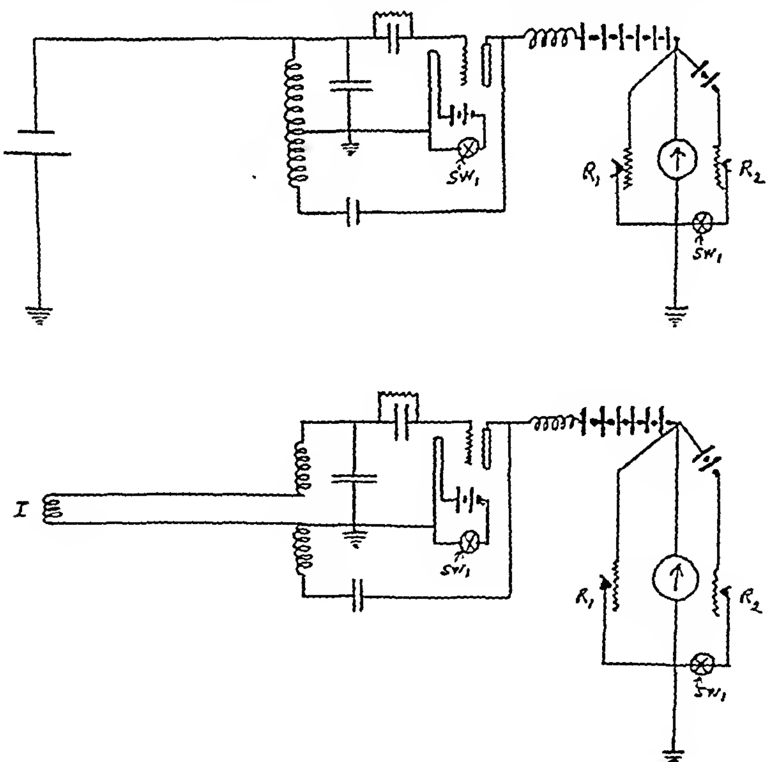

Fig. 1.

The device in question is based upon a modification of an electronic circuit previously described.[2] The schematic circuits here shown (Fig. 1) illustrate the

Received for publication, June 12, 1942.

modification employed in order to convert the circuit to its present adaptation. From examination of the two circuits it is obvious that the insertion of inductance I with the elimination of the capacity pick-up plate represents the principal change.

Inductance I is incorporated in the circuit by way of a shielded conductor cable one yard in length. It is a small solenoid affixed to the tip of a locator probe 12 inches in length, having a diameter of 0.8 cm., and in the present model is constructed of fiber rod provided with a sterilizable glass covering. The circuit constants are so adjusted that when the locator tip is brought into the presence or in contact with metallic objects characteristic directional deflections occur on the part of the indicating member of the milliammeter placed in the plate circuit.

Table I shows the discriminatory direction deflections obtained when contact is made with the materials listed. Of all the metals listed, iron or alloys of iron gave positive deflections, whereas the remainder of the metals gave negative deflections. There is evidence that for equivalent surface areas soft iron has a greater deflection factor than steel. Similar trends are apparent for metals which cause negative deflections. On the other hand, if discrimination is not desired, the circuit constants may be so adjusted to provide positive or negative deflection for all metals. Experimental evidence indicates that it is possible to "peak" the circuit in such a manner that maximum deflection may be obtained for any one of the series of metals listed.

A check of the maximum air distance between the tip of the locator and the objective for the recognition by demonstrable initial deflection was found to average 1 cm.; however, there existed some differences in this respect with each metal tested. The maximum air distance should be considered in a relative sense in view of the enhanced distance when using a larger probing inductance, and in view of the possibility of substituting a more sensitive meter in the plate circuit. On the other hand, a smaller probe possesses attributes not possessed by larger probes by virtue of its smaller size.

The surfaces of nonmetallic objects were tested, and the maximum air distance for a recognizable change was found to be very small—1 mm. or less—and in most instances contact was essential. In all objects or liquids tested a slight positive deflection occurred. As with the metals the deflection factor varied somewhat with each solution. When metallic objects were tested under water or other liquids, the directional changes noted on deflection were the same as those observed in air. The maximum water distance for recognizable initial change was at least as great as or greater than that found in air.

Experimental implantation of metallic iron and copper test objects (measuring 2 cm. by 2 cm. by 0.5 mm., 1 cm. by 1 cm. by 0.5 mm., 0.5 cm. by 0.5 cm. by 0.5 mm., and 0.25 cm. by 0.25 cm. by 0.5 mm.) was made in the dog. All implants of the above sizes were readily located beneath the skin—skin hair on or off, wet or dry. Deeper burial in the tissues beneath the surface of the skin were also readily located, provided the locator tip was within a distance of 1 cm. or less of the object. Similar implants placed in the abdominal cavity were also readily located.

Actual operation as a foreign body locator is as follows: Sw_1 is turned on. R_1 is rotated to introduce additional shunt resistance in parallel with the meter. The deflection of the meter is controlled to desired scale point by rotation of R_2. Locator is applied to region involved. On contact a small positive deflection occurs. The locator is then moved from one point to another, and any change in deflection, positive or negative, is noted. When such is manifested, the locator tip is manipulated in direction and depth in order to secure the maximum sustained deflection. When such is obtained, the tip of the locator is very near or in contact with the foreign metallic body. Maximum deflection results when the tip surface is parallel to the surface of the object and the minimum deflection results when the tip surface is at right angles to the surface of the object.

USE OF THE PHOTRONREFLECTOMETER FOR DETERMINATION OF THE OPTIMAL RATIO BETWEEN PNEUMOCOCCUS TYPE I SSS AND ANTIPNEUMOCOCCUS TYPE I RABBIT SERUM

Donald S. Martin, M.D., Durham, N. C.

INTRODUCTION

THE optimal proportions method of precipitin titration, introduced by Dean and Webb[1] in 1926, was based upon their observation that in a series of mixtures containing constant amounts of antiserum and varying amounts of antigen, the fastest precipitation occurred in that mixture which contained antigen and antibody in optimal proportions. Since this technique requires visual comparison of the relative reaction speeds in a number of tubes, its usefulness as a quantitative method of precipitin titration is limited. Consequently, more accurate evaluation of the quantitative relationships between antigen and antibody in the precipitin reaction[2] has resulted from the use of the objective quantitative chemical method of precipitate analysis described by Heidelberger and Kendall.[3]

Although the optimal proportions principle has been challenged on a theoretical basis by Heidelberger and Kabat,[4] the Dean-Webb procedure offers the only available means of determining separate antibody titers in sera containing more than one antibody when tested with solutions containing more than one antigen. Titration of individual antibodies in such a system is of great importance in the study of cross reactions, particularly in determining the proper absorbing dose of antigen. In absorbing an antiserum containing one or more antibodies with a solution containing multiple antigens, exhaustion of the homologous precipitins can be attained only by leaving a supernatant containing different concentrations of each antigen to interfere with subsequent tests for residue antibodies.

It was felt that the problem of precipitin titration in complex systems was of sufficient importance to justify the reinvestigation of the validity of the Dean-Webb optimal ratio. This paper describes a photoelectric method for recording the rate of precipitation and shows that the optimal proportions principle can be used for accurate precipitin titration. The application of the method to the titration of antibodies in complex antigen-antibody systems will be presented in a later paper. Since the photoelectric method has never before been applied to the problem of measuring precipitation rates in antigen-antibody mixtures, the technique is described in detail.

LITERATURE

Ramon[5] was the first to show that the antitoxin titer of a serum could be estimated by observing the first tube to flocculate in a series of tubes containing

*From the Departments of Bacteriology and Medicine, Duke University School of Medicine and Duke Hospital, Durham.

Aided by a grant from the John and Mary R. Markle Foundation.
Received for publication, June 25, 1942.

constant volumes of toxin and varying amounts of antitoxin. Dean and Webb[1] reversed the procedure, using a constant volume of serum and varying quantities of antigen. Marrack[6] has referred to these two methods as the alpha (constant antibody) and the beta (constant antigen) procedures. Brown[7] compared the two methods and introduced a third gamma procedure which was carried out after flocculation was complete in the beta series. The tubes were inverted twice, resulting in dispersion of the floccules in some of the mixtures. Brown concluded that there were three types of antigen-antibody reactions, which she described as follows: A type of reaction illustrated by the diphtheria toxin-antitoxin reaction, in which the alpha and beta flocculation zones coincided; that illustrated by the polysaccharide-antibody reaction, in which the alpha and beta methods yielded different flocculation zones but could be made to coincide by using the gamma technique; and that illustrated by the reaction between certain fractions of human serum and homologous antisera, in which the alpha and beta titrations differed and could not be made to agree by the gamma method.

The argument concerning the relationship of the alpha and beta optimal zones may have resulted from differences in opinion concerning the interpretation of the word "floccule." There is no logical basis for reasoning that the fastest reacting mixture in a constant antibody series should necessarily be the fastest reacting mixture in a constant antigen series. Flocculation, however, is a different phenomenon and is evidently related to the proportions of antigen and antibody in the mixture. This is suggested by Brown's[7] work showing that the floccules in certain mixtures could be dispersed after equilibrium had been established, bringing into agreement the different values obtained by the Ramon and Dean-Webb methods in the polysaccharide precipitin system.

The difficulties, inherent in the interpretation of results by either method, are illustrated by the work of Taylor,[8] who reported in 1931 that an optimal Dean-Webb ratio could be obtained for the horse serum antigen-antibody reaction, but that there was no optimal zone in the same system when titered by the Ramon technique. Increasing concentrations of antiserum caused only a speeding up of the reaction without any evidence of inhibition by excess antibody. In 1933, using horse serum and crystalline egg albumin as antigens, he[9] reversed his previous position and stated that the reaction was inhibited by antibody excess.

Although Dean and Webb stated that the optimal mixture was the fastest reacting mixture in a constant antibody-varying antigen series, the reactions in the tubes were described as proceeding from opalescence to turbidity, particulation, and finally flocculation. Since opalescence often appeared in several tubes simultaneously, they suggested that the optimal tube was detected easiest if the reaction were read shortly after particulation occurred, preferably at the time the particles were increasing in size. However, after equilibrium has been established in a constant antibody series, the greatest weight[1] and largest volume[10] of precipitate are found in mixtures containing excess antigen and not in the optimal reacting mixture. This emphasizes the fact that as the reaction progresses, there is a shift in particle size toward the region of antigen excess, suggesting that the mixtures should be compared as early as possible in the reaction.

Theoretical objections to acceptance of the Dean-Webb optimal proportions principle have been expressed by Heidelberger and Kabat[4] as follows: ". . . in a precipitation or agglutination reaction the factors influencing the velocity are imperfectly understood; (2) the position of the flocculation optimum is not independent of the dilution and varies whether the antigen or antibody be diluted; (3) in neither case is the optimum at the point of antibody exhaustion, so that the method gives no information as to the actual agglutinin or precipitin content of a serum."

Although the photoelectric method of measuring precipitation rates does not yield information concerning the actual speed of antigen-antibody union, differences in rate of formation of the light-reflecting precipitated particles can be determined and compared. Objections (2) and (3) are valid, since they refer to end points based on flocculation time and are subject to the differences in interpretation discussed above.

Certain technical difficulties are involved in preparing a series of mixtures for titration by either the Dean-Webb or Ramon method. For accurate visual comparison of the optimal and adjacent tubes, the mixtures should be made as nearly simultaneously as possible. As the ideal of simultaneous mixing is approached, accuracy in pipetting and mixing of the reagents must decrease. Conversely, precise measurement and thorough mixing cause a widening of the time interval between preparation of the various tubes in either series, creating difficulty in making satisfactory comparisons. Smith[11] discussed the problem in detail and suggested that the occurrence of double zones might be caused by improper mixing.

The method presented here avoids these difficulties, since each mixture is made separately and the speed of each reaction, measured by photoelectric means, is recorded permanently and is available for comparison at any time.

MATERIALS AND METHODS

Materials.—Pneumococcus type I polysaccharide was used in all experiments. The preliminary observations were made with a sample of dried polysaccharide furnished by Dr. A. F. Goebel and Dr. T. M. Rivers of the Rockefeller Institute for Medical Research. Another batch of material was obtained from the Lederle Laboratories through the courtesy of Dr. A. L. Joyner and Miss Frances L. Clapp. The polysaccharide was dissolved in sufficient 0.85 per cent saline (containing merthiolate 1:10,000) to make a concentration of 1 mg. per milliliter of solution.

The antiserum in all experiments was refined antipneumococcus type I rabbit serum furnished by the Lederle Laboratories. The antibody content of this serum, as determined in these laboratories, was 5.7 mg. antibody N per milliliter.

Apparatus.—Libby's[12] photronreflectometer was chosen because its usefulness in the precipitin reaction had been demonstrated by Libby[13, 14] and Bukantz, Cooper, and Bullowa[15] who showed that the pneumococcus polysaccharide content of a solution could be determined by observing the galvanometer deflection at a constant time interval after mixing. This instrument is constructed with a small black circular disk in the center of the photoelectric cell directly opposite the circular window of the chamber containing the mixture. Consequently, the

galvanometer reading is dependent upon the number of light rays deflected by particles in the chamber impinging on the periphery of the photoelectric cell.

Preliminary observations showed a short but definite lag in galvanometer response when a stable vaccine suspension was introduced into the apparatus. Before each experiment the galvanometer was adjusted to give a reading of 10 on the scale. Introduction of the clean empty chamber always caused a shift to a value between 2 and 3. The deflection of the empty chamber was determined before each experiment, and this value was subtracted from all readings made during the experiment.

Accuracy.—Sixteen determinations were made with a sample of diluted typhoid vaccine. Four different chambers were used, washed between each determination, and the readings were corrected for the deflection of the empty chamber. The highest deflection was 39.9, the lowest 38.3, the mean 39.0, and the standard deviation 0.40. Since the precipitation reaction involves two reagents and introduces errors in measurement, mixing, and timing, 10 separate experiments were done, using the same antigen and antibody solutions. Readings made five minutes after mixing showed a maximum of 56.6, a minimum 52.8, mean 54.0, and standard deviation 1.34.

Temperature Controls.—All experiments were done at room temperature (21° to 22° C.), the serum and antigen dilutions being kept in a room temperature water bath until used. However, it was observed that the temperature of the fluid in the chamber rose as much as 6° C. in five minutes if the apparatus had been used for seven or eight consecutive experiments. This was controlled partially by continuous passage of a stream of air through a tube inserted in one of the ventilating holes of the apparatus and disconnecting the machine from the electric current for a five-minute interval between experiments. The temperature rise was not eliminated but could be reduced to an almost constant value of 2.1° C. for each five-minute experiment.

Method of Mixing.—Mixing of antigen and antibody was accomplished by expelling 1.4 ml. of the antigen solution into a Wassermann tube containing 1.4 ml. of diluted serum. The mixture was drawn back into the pipette and expelled twice. The third filling of the pipette was transferred to the chamber previously placed in the apparatus.

Reading Times.—An assistant started a stop watch at the time the antigen solution was expelled into the serum. Galvanometer readings were made at ten-second intervals for the first minute, at fifteen-second intervals during the second minute, and at thirty-second intervals for the remaining three minutes. Except for the preliminary observations, all experiments were terminated five minutes after mixing.

Supernatant Examination.—After each experiment the chamber contents were poured into a Wassermann tube and placed in the icebox. After centrifugation the next morning, each supernatant was tested with three dilutions of antibody and three dilutions of antigen.

Calculations.—Each deflection was corrected by subtracting from it the deflection of the empty chamber. A second correction was made for the deflection caused by the control serum. Because of slight bubble formation, the introduction of control serum-saline mixtures caused an increase in deflection followed

by a slow drift back to a stabilized value in thirty to forty seconds. The control values at the appropriate time intervals were subtracted from all readings made during each antigen-antibody experiment.

EXPERIMENTAL

Effect of Flocculation on Galvanometer Deflection.—Since flocculation is followed by a settling out of the precipitate in the chamber, this experiment was planned to determine the effect of prolonged incubation on the galvanometer deflection. The data, obtained before the temperature control experiments were done, were not as accurate as those obtained later, but the results illustrated the limitations of the method after flocculation had occurred.

The mixtures were made in the usual way, but after recording the deflections for the usual five-minute periods, the contents of each chamber were poured into Wassermann tubes. At various intervals over a two-and-a-half-hour period, each mixture was shaken, placed in the chamber, and the deflection recorded.

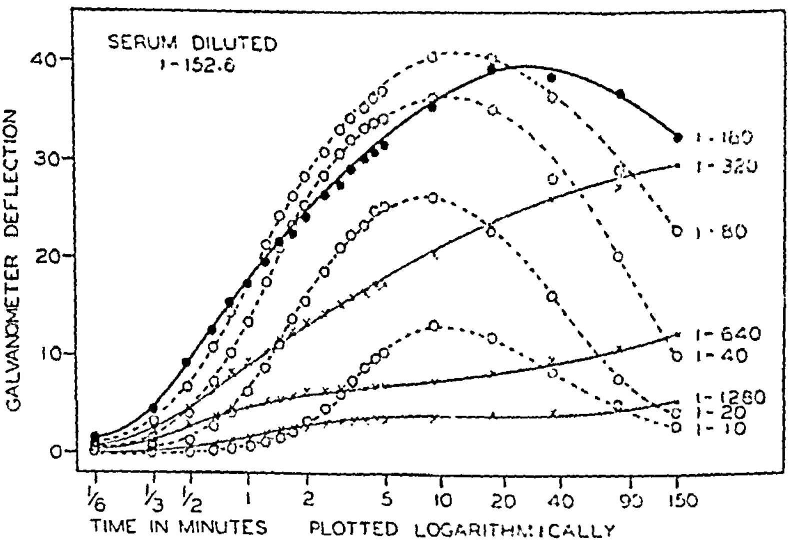

Fig. 1.—Deflection time curves obtained with constant amounts of antibody and various concentrations of antigen over a period of two and one-half hours. Open circles indicate excess antigen was found in the supernatant. Crosses indicate that excess antibody was found in the supernatant. Closed circles indicate that neither antigen nor antibody was found in the supernatant.

The results, plotted in Fig. 1, showed that if observations were continued over a long period of time there was a gradual falling off in galvanometer deflection in the optimal mixture and in mixtures containing excess antigen. Since settling of the precipitate was excluded by shaking of the mixture before placing in the chamber, the fall in deflection resulted from a decrease in the amount of light reflected from the precipitate due either to a reduction in surface-volume ratio or to the absorption of light rays by these very dense suspensions. The precipitates in these mixtures were large and flocculant in contrast to the finely divided turbid suspensions found in all mixtures containing excess of antibody. Although the falling deflection indicated floccule formation, there was no sharp end point and flocculation time could not be estimated. Since none of the mix-

tures showed a decrease in galvanometer deflection during the first five minutes of observation, all subsequent experiments were terminated at this time interval after mixing.

Optimal Proportions in Various Antigen and Antibody Concentrations.—Each of 11 serum dilutions, varying from 1:6.25 to 1:200, was tested with nine concentrations of antigen, varying from 1:5 to 1:1,280 dilutions of the stock solution containing 1 mg. of polysaccharide per milliliter. All dilution figures in the tables and charts are corrected to give the concentration of each reagent per milliliter of mixture.

Excess antigen	−	−	−	−	−	−	+	+	+
Excess antibody	−	+	−	+	−	−	−	−	−

In Table I are listed the corrected galvanometer deflections obtained with a constant amount of serum (final dilution 1:100) and varying amounts of antigen. The data for all constant antibody series were similar. These data are plotted in Fig. 2 as deflection-time curves to show the progress of the reaction for each antigen dilution. Initially, the most rapid precipitate formation occurred in the mixture containing antigen diluted 1:80 (closed circles), the supernatant of which contained neither antigen nor antibody. With smaller amounts of antigen (region of antibody excess) the precipitate formed more slowly (crosses). The maximal five-minute reading was obtained with antigen diluted 1:40, the supernatant of which was found to contain an excess of antigen (open circles). This dilution of antigen, however, caused a slower initial rate of precipitation than that observed with the optimal antigen dilution. More concentrated antigen resulted in a further slowing of the reaction and a lower galvanometer deflection at the end of the experiment. This was confirmed by all constant antibody series in which the deflections did not exceed the limits of the galvanometer scale during the five-minute period of observation.

The crossings of the time-deflection curves in these experiments illustrate the dangers of interpreting results from a single observation at a single time interval. For example, the same dilution of serum (1:100) will give the same

reading (approximately 20) at the same time interval (approximately one hundred and forty seconds) after mixing with antigen diluted either 1:160 or 1:10. It is obvious that one must know either the shape of the curve or work only within a specified range.

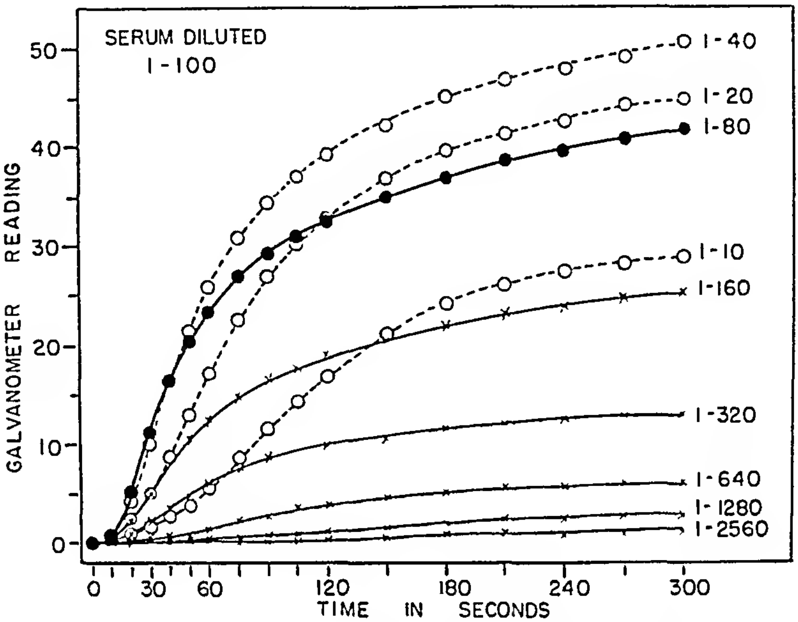

Fig. 2.—Deflection time curves obtained with constant amounts of antibody and varying dilutions of antigen over a 5-minute period. Symbols are the same as in Fig. 1.

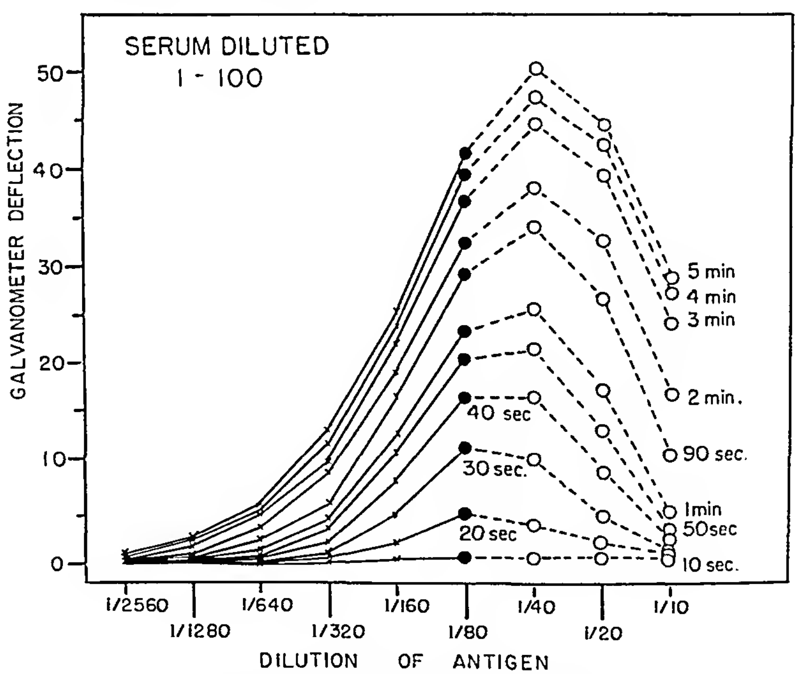

Fig. 3.—Deflection-antigen dilution curves obtained at various time intervals after mixing. Symbols are the same as in Fig. 1.

In Fig. 3 these same data are plotted more conveniently with antigen dilutions as abscissae. This shows again that the 1:80 antigen dilution precipitates fastest during the first thirty seconds. At forty seconds the 1:40 dilution has caught up with the optimal dilution, and after fifty seconds the greatest deflection is obtained with the 1:40 dilution.

TABLE II

CORRECTED GALVANOMETER DEFLECTIONS OF THE LEADING AND ADJACENT TUBES FOR VARIOUS DILUTIONS OF ANTIGEN AND SERUM AT SIGNIFICANT TIME INTERVALS

SERUM DILUTION	TIME IN SECONDS	ANTIGEN DILUTION						
		1:640	1:320	1:160	1:80	1:40	1:20	1:10

1: 70.66	10				2.1	*2.7*	2.0	0.9
1: 70.66	50				27.2	36.0	*36.4*	22.3
1: 50	10					15.0	*17.0*	9.6
1: 35.33	10					32.8	*41.3*	39.6
1: 25	10						57.1	*Off scale*

The deflections of the optimal mixtures are italicized.

The optimal ratios obtained over a fairly wide range of serum dilutions are illustrated by the data presented in Table II. A deflection of 1.0 scale unit was chosen arbitrarily as the smallest value indicating a significant difference in the amount of precipitate. The data in this table were selected to show only the deflections of the optimal and adjacent tubes at the earliest time intervals that significant differences could be measured. The deflection and shifting times of the optimal tube to the mixture containing more antigen are included. These data are plotted in Fig. 4, which shows the results of testing the supernatants for antigen and antibody and indicates the straight line relationship of the optimal tube to both the antigen dilution and the serum dilution. It illustrates also the important point that except in the region of concentrated antibody, the first tube to show definite precipitation lies in the region in which neither antigen nor antibody is present in the supernatant. The maximal five-minute deflection, however, occurs in the region of antigen excess.

Constant Antigen-Varying Antibody Series.—The data, rearranged to compare the reaction speeds obtained with constant amounts of antigen and varying concentrations of antibody, showed that no antibody dilution was optimal for any concentration of antigen. The speed of the reaction increased as the antibody concentration was increased, and in no instance did excess of antibody cause inhibition of the precipitation rate (Fig. 5).

Relationship of Antigen Concentration to Galvanometer Deflection in Region of Serum Excess.—The observations of Bukantz, Cooper, and Bullowa[15] are confirmed by the data presented in Table III, giving the five-minute readings obtained in the regions of serum excess. For antigen dilutions varying from

1:1,280 to 1:160, the galvanometer deflection was directly proportional to the antigen concentration, provided serum was greatly in excess. One unit on the scale represented an average concentration of 0.25 gamma of polysaccharide per milliliter of mixture. These data are plotted in Fig. 6, using the logarithm of the five-minute readings to show the straight line relationship between the log

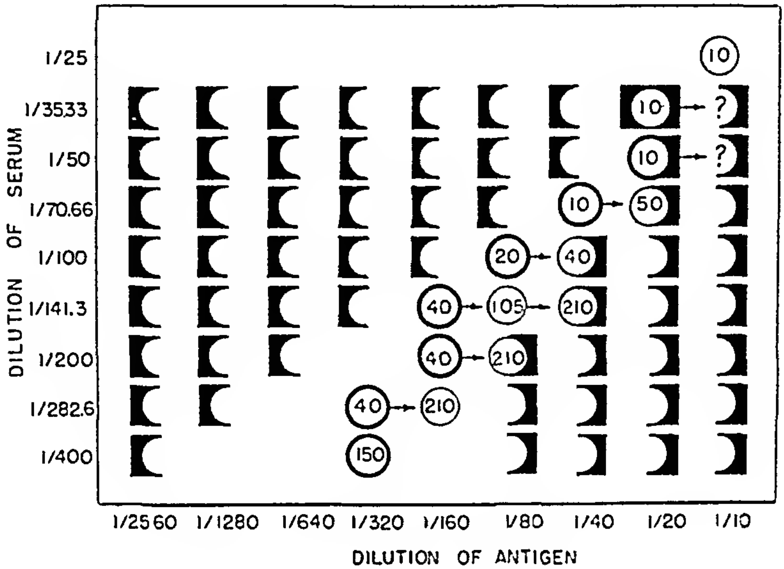

Fig. 4.—Optimal antigen dilutions for varying dilutions of serum. The figure within each circle represents the earliest time interval after mixing at which the deflection of the indicated mixture was significantly higher than deflections obtained at the same time interval with other concentrations of antigen. The results of supernatant examinations are shown by the semicircles, those on the right of the chart indicating excess antigen and those on the left, excess antibody.

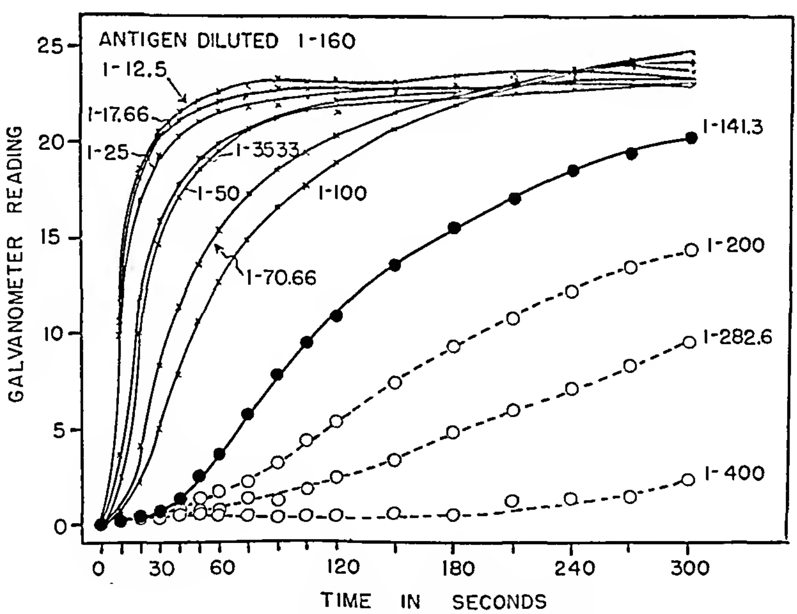

Fig. 5.—Deflection-time curves obtained with constant amounts of antigen and varying amounts of antibody. Symbols are the same as in Fig. 1.

of the deflection and the log of the antigen concentration. This chart includes also the results obtained in the region of excess antigen (open circles) and the optimal antigen concentration (closed circles). Maximal deflections within five minutes were not attained, as a rule, in the optimal mixtures, but it is possible that these mixtures might have attained the same deflection as those with excess of antibody if observations had been continued for a longer period.

DISCUSSION

No conclusions can be drawn from these experiments concerning the actual rate of reaction between antigen and antibody. The instrument records only the amount of light striking a photoelectric cell after reflection from particles precipitated during the reaction, and there is no evidence that the galvanometer deflection is a function of the weight or the volume of the precipitate. Further-

more, no significance can be attached to the shape of the deflection time curves because the increase in deflection can result from an increase in the number of particles of uniform size, increase in size of a uniform number of particles, or a summation of both factors.

Although the purpose of these experiments was to develop a procedure which could be applied to the problem of precipitin titration in complex antigen-antibody systems, the results indicate that it has certain advantages over other accepted methods of quantitative analysis. Since the optimal proportions principle is valid over a wide range of antigen-antibody dilutions, titration requires only one dilution of serum. With the refined antipneumococcus type I antibody used in these experiments, a complete titration was possible with 14.0 ml. of a 1:100 dilution of serum.

The method is not only more economic of materials but is less time-consuming, a complete run requiring approximately two hours. In comparison with the Dean-Webb procedure the photoelectric method is much more advantageous because it allows time for accurate measurement and thorough mixing of materials. It removes also any doubt concerning the optimal time for reading the reaction, since these experiments have demonstrated that the optimal ratio is determined by noting the fastest reacting mixture as early as possible in the reaction. If the reactions are compared later, the greatest deflection is found in the region of antigen excess.

The optimal ratio, as determined by this method, probably corresponds to the equivalence point described by Heidelberger, since Culbertson[16] showed that the "neutralization" point, as determined by absence of both antigen and antibody in the supernatants, agreed with the results obtained by the chemical method of analysis. A further agreement between the optimal ratio method and the chemical method is evidenced by calculation of the number of molecules of antigen and antibody reacting at the optimal point. Assuming a molecular weight of antibody to be 160,000, the number of molecules in 0.01 ml. of this serum, containing 5.7 mg. of antibody N, or 35.62 mg. antibody protein per milliliter is 13.5 by 10^{14}. The antigen dilution optimal for 0.01 ml. of serum contains 0.0125 mg. SSS per milliliter. Assuming a molecular weight of 5,000, this antigen dilution can be calculated to contain 15.1 by 10^{14} molecules of SSS per milliliter, suggesting that the antigen and antibody molecules combine in a 1:1 ratio when mixed in optimal proportions.

Culbertson[16] emphasized the great inaccuracies of the popular antigen-dilution method of precipitin titration, based upon observing the greatest dilution of antigen causing a visible precipitate with constant amounts of antibody at equilibrium. His contention that such a method was applicable to the titration of antigen content and not to the determination of antibody content is confirmed by these experiments which demonstrate that if excess antibody is present, the galvanometer deflection after a suitable time interval is dependent on antigen concentration alone. Bukantz, Cooper, and Bullowa[15] suggested that the antibody content could be estimated by observing the galvanometer deflection at a constant time interval and noting the concentration of antigen yielding the maximal deflection. However, the maximum deflection in a constant antibody

series is attained always in the region of antigen excess and, therefore, cannot be used as a measure of antibody concentration.

SUMMARY AND CONCLUSIONS

A photoelectric method for determining the relative precipitation rates obtained with various concentrations of antigen and antibody is described. The advantages of this method over the original procedure described by Dean and Webb may be summarized as follows:

1. The various dilutions of antigen and antibody can be measured accurately and mixed thoroughly.

2. The relative precipitation speeds can be determined early in the reaction at the stage which has been shown to be the optimal time for comparing the various precipitation rates.

3. The data are obtained objectively and can be recorded permanently.

From a study of eleven constant antibody-varying antigen series, using pneumococcus type I polysaccharide and antipneumococcus type I rabbit serum, it has been shown that:

1. The fastest initial precipitation occurs in the mixture in which antigen and antibody are in optimal proportions, as shown by absence of both reagents in the supernatant.

2. The maximum galvanometer deflection is obtained in the region of antigen excess.

3. The galvanometer deflection five minutes after mixing is directly proportional to the antigen concentration, provided excess antibody is present.

Comparison of the rates of reaction obtained in nine constant antigen-varying antibody series shows that no dilution of antibody is optimal for a constant amount of antigen. Progressive increases in antibody concentration result in progressively faster precipitation, excess antibody causing no inhibition of the reaction.

The close agreement of Heidelberger's "equivalence point," Culbertson's "neutralization point," and the optimal ratio, as determined by this method, are discussed.

THE KAHN VERIFICATION TEST IN MALARIA

ALBERT DE GROAT,* CAMP RUCKER, ALA.

KAHN has recently published a verification test[1] for the detection of false positive reactions in the serology of syphilis. More recently, Kahn, McDermott, and Marcus[2] and Jacobsthal[3] have reported that this test is capable of differentiating positive serologic reactions in syphilis from those occurring in malaria. An opportunity was afforded me to apply the verification test to a group of clinically nonsyphilitic soldiers with malaria who gave positive serologic reactions for syphilis. This article will present the results obtained.

The verification test is based on the principle that syphilitic serums giving positive serologic reactions show under proper conditions more marked precipitation at 37° than at 1° C. (syphilitic type of reaction), while nonsyphilitic serums giving positive reactions show under the same conditions more marked precipitation at 1° than at 37° C. (general bio-

logic, nonsyphilitic, type of reaction). Serums giving negative serologic reactions generally show no precipitation at 37° or 1° C., and the verification reaction is referred to as negative type. When precipitation of equal strength is obtained at these two temperatures, the verification results are referred to as inconclusive.

Blood specimens from the seropositive cases of malaria and also from some seronegative cases were sent to Doctor Kahn's laboratory at the University of Michigan Hospital for verification tests. No indications as to the source of these specimens were submitted. The serologic reports received from that laboratory are summarized in Table I. Of eighteen serums examined, the standard Kahn test proved to be positive in seven, doubtful in one, and negative in the remaining ten. The supersensitive presumptive test gave ten positive reactions in the same group of serums. All these positive reactions, according to the verification test, were of the general biologic (nonsyphilitic) type, except in one instance in which the result of the verification test was reported as inconclusive.

1/30/42	Neg.	Neg.	0	Negative

Of interest is the fact that five of the negative reactions with the standard and presumptive Kahn tests were also, according to the verification test, of the general biologic (nonsyphilitic) type. Generally, serums that give negative reactions with serodiagnostic tests give the negative type of reaction with the verification test. The general biologic type of reaction given by these negative reacting serums indicates, according to Kahn, that these serums contain nonsyphilitic "antibody" and that they might give positive reactions with certain serodiagnostic tests and, under certain conditions, with perhaps all tests.

Of interest is the fact also that, according to Table I, malarial serums may give high titers with the quantitative Kahn reaction. Two of the serums gave a titer of 40, one of 80, and one of 200. Evidently positive reactions in malaria are not limited to low serologic titers.

The next problem that presented itself was to find if the general biologic (nonsyphilitic) type of reactions obtained in the patients with malaria could be accepted as serologic evidence of the absence of syphilis in these cases. Repeated serologic examinations of the blood specimens in these cases, it was believed, would throw light on this problem. Thus, positive serologic reactions in acute malaria generally become negative after recovery. Would the positive reactions in the patients under investigation persist or would they become

negative with the subsidence of the fever and with recovery? Accordingly, arrangements were made for the serologic follow-up of these patients.

Table II lists seven seropositive cases of malaria which became seronegative in about one to three months. The verification reactions in these patients changed from the general biologic type to the negative type of reactions. An exception is Case 1 in which the original general biologic type of reaction persisted. Table III lists five cases of malaria, essentially seronegative, except that with the supersensitive presumptive test, seven positive reactions of varying degree were obtained through the period of investigation. In these cases also, the verification test at first gave the general biologic type of reactions, and later, the negative type.

Two febrile patients of the original group of twenty-one, listed in Table IV, were found not to have malaria. One patient with cellulitis (Case 13) was Kahn-negative. Another (Case 14), with an acute respiratory infection, was Kahn-positive. The verification test, in both cases, gave the general biologic type of reactions. On repeated serologic examinations, the Kahn-positive reaction rapidly became negative. But in both cases, the general biologic type of verification reactions persisted, although the patients had recovered. It was impossible to continue verification studies in these patients due to the transfer of the soldiers from Fort Custer.

SUMMARY

The Kahn verification test was applied to a group of clinically nonsyphilitic soldiers with malaria giving positive serologic reactions for syphilis. It was found that these soldiers gave the general biologic (nonsyphilitic) type of reactions, indicating that the verification test can be employed as an aid in establishing the differential diagnosis of malaria and syphilis.

DETERMINATION OF BLOOD PRESSURE IN RATS BY DIRECT OBSERVATION OF BLOOD VESSELS*

George W. Duncan, M.D., Baltimore, Md., and Chester Hyman, M.S., and Edward L. Chambers, B.A., New York, N. Y.

Although several methods of determining blood pressure in small animals have been described, certain complicating features in the technique of each of them often render them inapplicable to the experimental problem on hand. It is the purpose of this communication to point out briefly the essential features of previously described methods and to present a simple method for repeated determinations which produces no trauma or loss of blood and which may be used on either anesthetized or unanesthetized animals.

Methods involving direct cannulation of large vessels require either local or general anesthesia. Trauma and loss of blood result to a greater or lesser degree during exposure and cannulation of the vessel, and in most of the methods of this type the animal is usually sacrificed. The method of Woodbury and Hamilton[1] has definite advantages in some problems but is not simple technically, the apparatus is expensive, and each determination requires surgical exposure of the vessels to be punctured. The values obtained by these investigators are higher than pressures obtained, also by arterial cannulation, by Rous and Drury[2] and by Chanutin and Ferris.[3] Diaz and Levy[4] described a method for determining blood pressure in rats which depends upon the flow of blood from the incised tail when the pressure in the arteries exceeds that in a pneumatic cuff about the base of the animal's tail. The values obtained by these authors coincided rather closely with pressures obtained by aortic cannulation. This method produces loss of blood and trauma with each determination, and where frequent determinations are made, this degree of blood loss may complicate certain types of experiments.

Indirect methods which necessitate no trauma or loss of blood have been described by several authors. Kunstmann[5] and Bonsmann[6] made use of the restoration of pink color due to the return of blood to a limb or tail which has been previously emptied of blood by a tight bandage. The flow of blood is controlled by means of a compression cuff at the base of the animal's tail. The values obtained by both these investigators are lower than the values reported by other investigators. Williams, Harrison, and Grollman[7] have described a practical and accurate method which is based on plethysmographic measurement of the increase in volume of the rat's tail when the pressure in the arteries exceeds that in a compression cuff about the animal's tail. This method is used on trained rats and requires preliminary warming of the animal for accuracy. A similar method was described by Byrom and Wilson.[8]

*From the Department of Surgery, The Johns Hopkins University, and Department of Biology, Washington Square College, New York University.

Received for publication, Sept. 11, 1942.

Two methods have been described which involve the application of a compression cuff to the thigh and observation of the flow of blood in the small blood vessels of the foot. Griffith[9] observed microscopically the cessation and restoration of flow in the small superficial vessels on the dorsum of the rat's foot. The observations were made with strong reflected light on an area that had been depilated and cleared with immersion oil. He recommended that several fields be observed because of the uncertainty of the type of vessels under observation. We were unable to obtain consistent results by this method. McMaster[10] reported a similar method in which flow in the blood vessels at the base of the claws of mice was observed by transmitted light. He pointed out that similar observations cannot be made in rats, even in young ones.

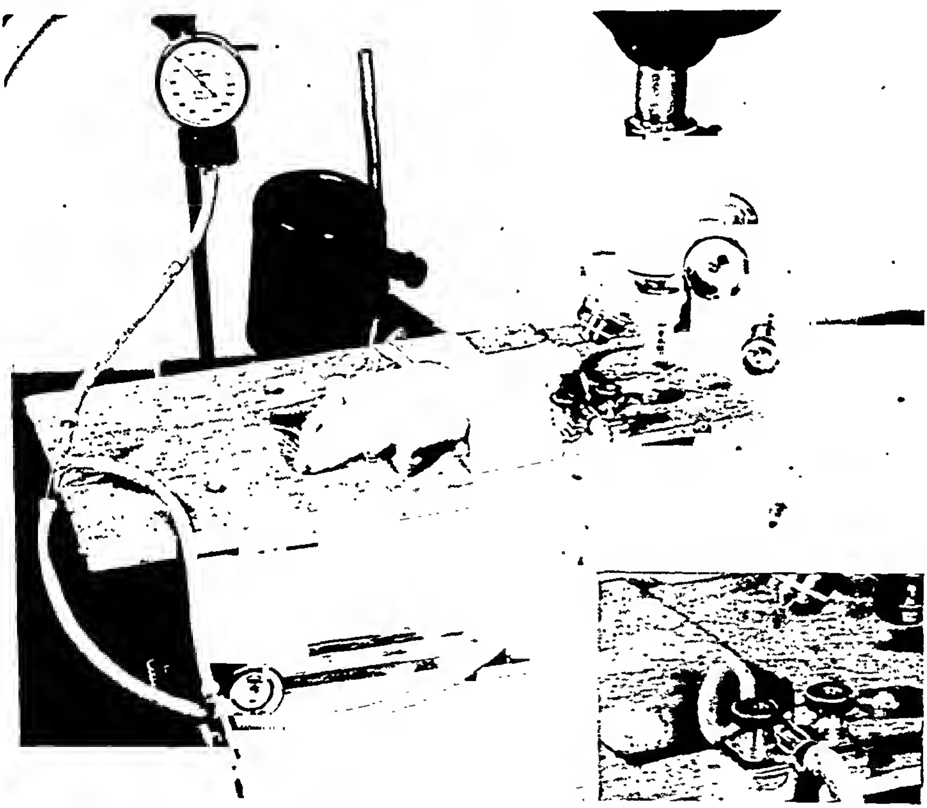

Fig. 1.—Arrangement of apparatus for determining blood pressure of rat. Insert shows details of pressure cuff and transillumination cone.

The method to be described is also based upon direct observation of blood vessels. The vessels are those of the translucent interdigital web and are observed by means of transmitted light. These vessels of the spread-out web are clearly visible so that the different types of vessels can be easily identified.

Normal rats weighing from 130 to 200 Gm. were used. The apparatus, shown in Fig. 1, consists of a cuff, similar to that described by Diaz and Levy[4] and Byrom and Wilson,[5] which is placed about the thigh. The cuff is made of a 2 cm. length of glass tubing 2 cm. in diameter and flanged on both ends, with a short length of 4 mm. glass tubing fused to the side for connection with a manometer and a rubber pressure bulb. A piece of ⅝ inch Penrose tubing

is placed inside the larger glass tube, everted over the flanged ends, and cemented to the outer surface. The cuff is attached to a board 5 by 12 inches in such a position that it rests about four inches from the end. The unanesthetized rat is kept fairly quiet by placing it in a snugly fitting glass cylinder on the end of the board carrying the cuff. One hind limb is drawn through the cuff to the level of the upper thigh and held in place by small clamps attached to the claws or by strings tied about the distal ends of two adjacent digits. The position of the foot is such that the spread-out interdigital web rests upon the upper surface of truncated glass cone fixed through the board. The cone measures approximately 1 cm. at its base, and its upper end is ground to a triangular cross section which measures approximately 0.25 cm. on each side and fits closely between the outspread digits. The web is rendered translucent by removal of the epidermal scurf by a brief application of depilatory cream and clearing with almond oil or paraffin oil. A small piece of cover slip placed upon the web serves to hold the film of oil in place and thus an even surface for observation is presented. The board with the animal in place is mounted on the stage of the microscope so that the truncated cone of glass lies in the optical axis. Light is obtained from a Leitz low voltage microscope lamp or any equivalent source. With a magnification of 100 times the vessels and the flow of blood can be clearly seen. The small arterial vessels can be differentiated from corresponding veins by their relatively thicker walls and more rapid rate of flow and by the direction of flow.

In making a determination the cuff is inflated to a pressure sufficient to stop all flow of blood. The pressure is then slowly lowered until the first continuous flow becomes visible in the arteriole under observation. The pressure at that time is taken as the blood pressure in the large arteries of the thigh. Other vessels in the field are checked to ensure accuracy.

The normal blood pressures of different animals of the unanesthetized group ranged from 90 to 140 mm. Hg. The range of pressures in different animals of the anesthetized group was from 70 to 120 mm. Hg. Repeated determinations were made on several animals of each group and were found to agree within 4 mm. Hg in any given animal. The accuracy of the method was checked by obtaining pressures by aortic cannulation on six rats immediately following determinations by the interdigital web method. The values checked within 5 mm. Hg.

SUMMARY

The arterial blood pressure of rats may be rapidly and easily determined by microscopic observation of the flow of blood in the small arterial vessels of the interdigital web. Values obtained by this method agree with pressures determined by aortic cannulation and with those reported in the literature.

A METHOD FOR OBTAINING RECORDS OF THE TORTOISE SINUS WITH DATA ON EXTRASYSTOLES AND LENGTH OF CYCLES FOLLOWING STIMULATION

FREDERICK E. EMERY, PH.D., AND T. A. LOOMIS, M.S., BUFFALO, N. Y.

During the last several years graphic records taken from the beating sinus venosus of the tortoise have been used in discussing with medical students the refractory period, extra systole, and compensatory pause of the heart. These phenomena in the ventricles and to some extent in the auricles are common descriptions in most textbooks, and a discussion of excitations near the great veins or sinoauricular node is nicely presented by Wiggers.[1] Graphic records taken from the sinus are not shown in any of the present textbooks, nor have we found them in any of the literature so far reviewed. It seems worth consideration, therefore, to describe briefly the method used to obtain records of the sinus venosus and to exhibit some of the records obtained. The literature is, for the most part, of long standing, and excellent reviews are available.[2, 3] These and original contributions having a direct bearing on the problem are discussed briefly as their citation appears in the body of this paper.

PROCEDURE

Twenty-seven pithed tortoises about six inches in shell length were used, and from these about two thousand records of sinus stimulation were saved for study. The usual method of recording the auricular and ventricular contraction by means of aluminum heart levers was employed. In order to obtain tracings of the beating sinus, fine thread was usually attached directly to the sinus (5 to 8 mm. to the right of the midline) with the aid of fine-pointed dissecting forceps. In a few cases the thread was placed around the large veins to the right of the sinus. The heart lever required careful counter balance and adjustment, but when so arranged usually gave a clear tracing of the sinus beats. By means of a small, bent glass rod with a hook at the end the base of the ventricle could be adjusted to the left and ventrally in such a way

Department of Physiology, University of Buffalo.
Received for publication, July 6, 1942.

as to free the sinus tracing from auricular and ventricular interference. One stimulating electrode of fine copper wire was placed on and sometimes directly into the wall of the sinus, and the second electrode was stuck in the liver one inch back from the heart and on the midline. Make-and-break stimuli from a Harvard inductorium were given. Best results were obtained if the heart rate was slow, so in six experiments the rates were slowed by placing the shell on ice during the entire experiment. A depression in a large cake of ice was chipped out to fit the contour of the shell and, when the tortoise was placed in this, satisfactory slowing of the heart rate soon followed.

RESULTS

Tracings taken simultaneously from the sinus, auricles, and ventricles show the normal sequence of activity in these respective parts as the contracting wave moves over the heart.

Fig. 1*B* shows that stimulation of the sinus in the middle third of the cycle with a relatively weak stimulus (make) has no effect on the rhythm, while the break stimulus applied at the same time of the cycle produced an extra con-

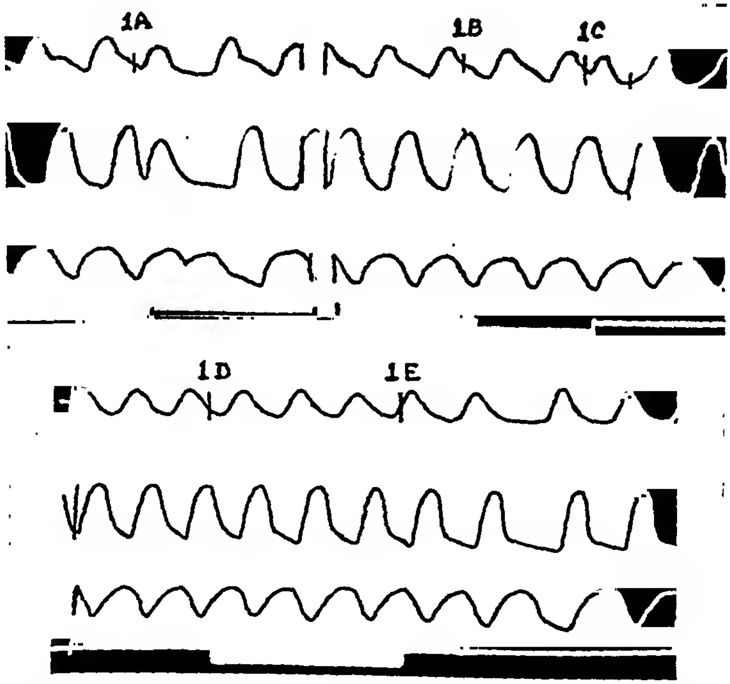

Fig. 1.—Heart rate, 17 per minute. Tracings from above downward; sinus, auricles, ventricles, signal magnet (down stroke make stimulus, up stroke break stimulus). Arrows show where the stimulus was applied to the sinus (one dry cell, Harvard coil, 4 cm.).

A, A stimulus applied to the sinus in the last third of diastole induced an extrasystole. The pause following is longer than normal. The "postcompensatory" contraction of the sinus is higher than normal.

B, A make stimulus, just below threshold for this tortoise, applied to the sinus in the middle third of the cycle had no effect.

C, The break stimulus applied in the same phase of the cycle as in *B* was followed by an extrasystole and a pause of shorter duration than normal. The "postcompensatory" contraction of the sinus is slightly higher than normal.

D, A make (in this case subthreshold) stimulus applied in the last third of the cycle had no effect.

E, Since the make stimulus as in *D* was subthreshold, the break stimulus as applied was relatively weak, yet the disturbance induced by stimulation in the refractory period caused the next three pauses of the sinus to be longer.

traction in the auricles and ventricles (Fig. 1C). In this case the extra contraction of the sinus was followed after a pause of shorter duration than normal by the usual rhythmic sinus discharges. Lewis[3] describes sinus extrasystoles as rare in the human subject but points out that the returning cycle may be shorter than normal. Engelmann[4] showed in amphibians that an extrasystole induced by stimulating the sinus was followed by returning cycles of the same length as the initial cycles. In our experience if the stimulus is applied to the sinus in the middle half of the cycle, the pause following the extrasystole may be of normal length about 20 per cent of the time or, using the expression of

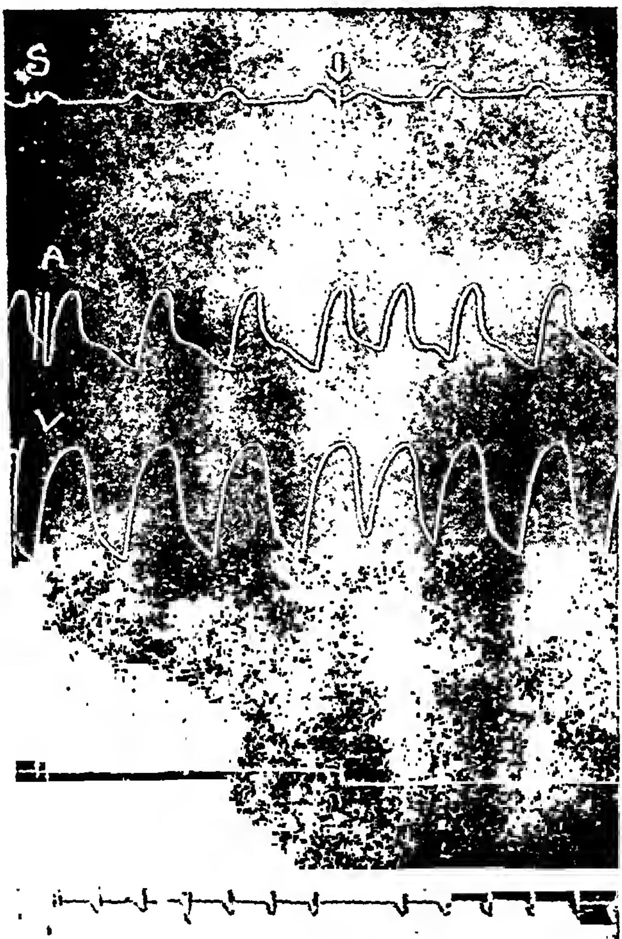

Fig. 2.—Time in 5 seconds, otherwise tracings and coil same as in Fig. 1. A stimulus applied at the beginning of the middle third of the cycle induced an extrasystole of the sinus which was carried to the auricles and ventricles. This induced cycle was approximately equal in length to the preceding cycle.

Lewis, the returning cycle is approximately equal in length to the initial cycles (Fig. 2). On the other hand, the next discharge of the sinus, after the extrasystole, may be delayed as compared to initial cycles or subsequent returning cycles (Figs. 1A, 3 A and B, 4B). Cushny,[5] working with the isolated ventricle of mammals, introduced the idea of fatigue of the pacemaker due to extra impulses either from artificial stimuli or "impulses reaching it from the

Keith-Flack node.'' Lewis[3] has discussed this point in regard to the sinoauricular node and states that ''The manner and circumstances in which this depressant effect of an extrasystole is exerted are not yet entirely clear.''

In order to study factors which might determine the length of the pause following an extrasystole of the sinus, 772 records were carefully measured with the aid of compass and lens. This study revealed that a stimulus applied to the sinus during contraction (refractory period) always failed to cause an

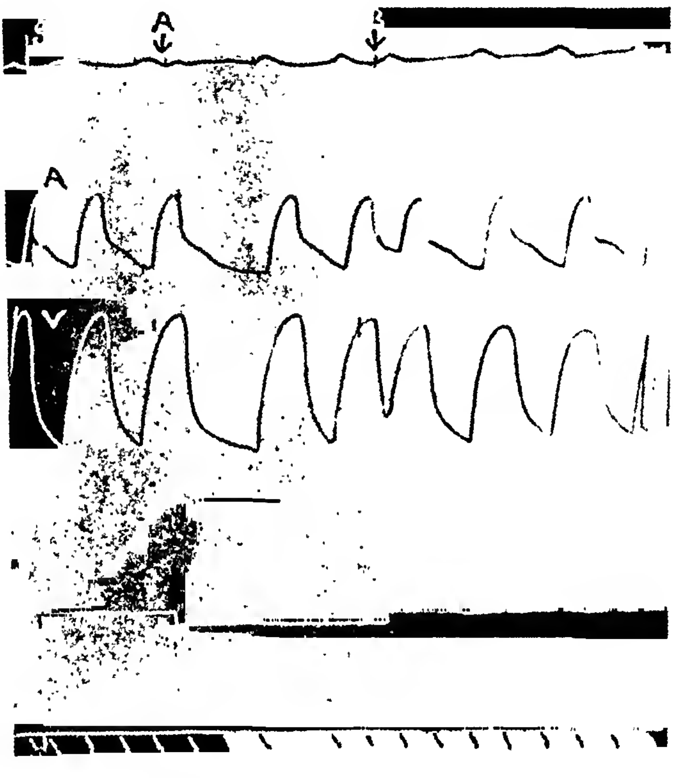

Fig. 3.—Time in 5 seconds, otherwise tracings and coil same as in Fig. 1.

A, Stimulus applied to the sinus at the beginning of the middle third of the cycle. Extra contraction of the sinus not carried to the auricles and ventricles. "Postcompensatory" contraction of auricles and ventricles higher than normal. Induced cycle slightly longer than the preceding cycle.

B, Stimulus applied in the middle third of the cycle. Extrasystole of the sinus carried to auricles and ventricles, followed by a pause of longer duration than normal.

extra contraction but the rhythm may be disturbed. In about one-fourth of the records the next pause was longer (Table I), and sometimes this disturbance was evident in the next two or more following cycles (Fig. 1*E*). A stimulus of at least threshold strength for the sinus but applied during the relaxation of the sinus (descending limb of the record) often induced a change in rhythm, and the subsequent pause was altered, being shorter in a few records (3.4 per cent), normal in 53.0 per cent, and longer in 43.6 per cent (Table I). This period may be looked upon as the relative refractory period and variable in length as subsequent discussion will show.

A stimulus applied in the first quarter of the cycle usually gave no extrasystole, but in a few cases where an extrasystole occurred the pause that

followed was always of shorter duration than normal. Table I shows a summary of nineteen records of tortoises in which this type of response occurred. A stimulus falling within the first third of the cycle gave an extrasystole which was followed in 77.1 per cent by a pause of shorter duration than normal and in 9.4 per cent by a longer pause than normal (Table I). A stimulus applied during the middle third of the cycle gave an extrasystole and a pause which was shorter than normal in 54.1 per cent. In contrast to these examples, a stimulus given in the last third of the cycle caused as expected an extrasystole, but the pause that followed was usually (80.0 per cent) longer than normal (Table I).

TABLE I

The length of 772 cycles following stimulation is compared to the previous cycle. In records of tortoises in which the stimulus was not applied in the refractory period or relative refractory period, the following cycles included an extrasystole in each case.

STIMULATED IN:	NO. OF RECORDS	LENGTH OF NEXT CYCLE FOLLOWING EXTRASYSTOLES OR STIMULATION		
		SHORTER	SAME	LONGER
Refractory period	100	0	77	23
Relative refractory period	87	3 (3.4%)	46 (53.0%)	38 (43.6%)
First quarter of cycle	19	19	0	0
First third of cycle	96	74 (77.1%)	13 (13.5%)	9 (9.4%)
Middle third of cycle	270	146 (54.1%)	56 (20.7%)	68 (25.2%)
Last third of cycle	200	17 (8.5%)	23 (11.5%)	160 (80.0%)

Thus it is clear that the length of the pause that follows an extrasystole in the sinus of the tortoise is not fixed but closely related to the time in the cycle when the stimulus was applied (Figs. 1 to 4). The earlier in the cycle that an effective stimulus is applied, the shorter the pause is likely to be, and conversely a stimulus applied in late diastole of the sinus is almost certain to be followed by a pause of longer duration than normal. At least two factors have been found that tend to change these expected results. The first of these deals with the relative refractory period of the sinus which, in our experience, varied in length in different tortoises. When this period is long, it is most difficult to obtain an extrasystole sufficiently early in the cycle to give the expected pause of shorter duration. Fig. 4*A* illustrates this very nicely and shows that a make stimulus applied in the middle third of the cycle had no effect. After a pause of a few seconds a second record was taken, and the same strength of stimulus applied slightly later in the cycle induced an extrasystole which was followed by a pause of longer duration than normal (Fig. 4*B*). In other words, it was impossible to get a reaction in the first third of the cycle with a stimulus which was considerably above threshold. The second factor also tends to fix the length of the pause but operates when the stimulus is applied in late diastole of the sinus. In these records the induced or extrasystole occurred at the expected time of the normal contraction and was followed by a pause of normal length.

The disturbance in the sinus induced by stimulation may be followed by a delay of the next rhythmic discharge, even though the artificial stimulus may have been so weak that the sinus contracted only slightly (Fig. 3*A*). This record also shows that the stimulus was either too weak to be effectively transmitted to the auricles or the auricles had not recovered sufficiently to respond.

the result being a pause in auricular and ventricular activity until the next sinus discharge, which was itself delayed. The strength of the stimulus has some effect on the length of the pause that follows an extrasystole. If the stimulus is very strong, the pause is likely to be modified in the direction of longer length. However, careful check of many records shows that the strength of the stimulus within reasonable limits does not alter the expected results in regard to the length of the pause that follows the extra contraction.

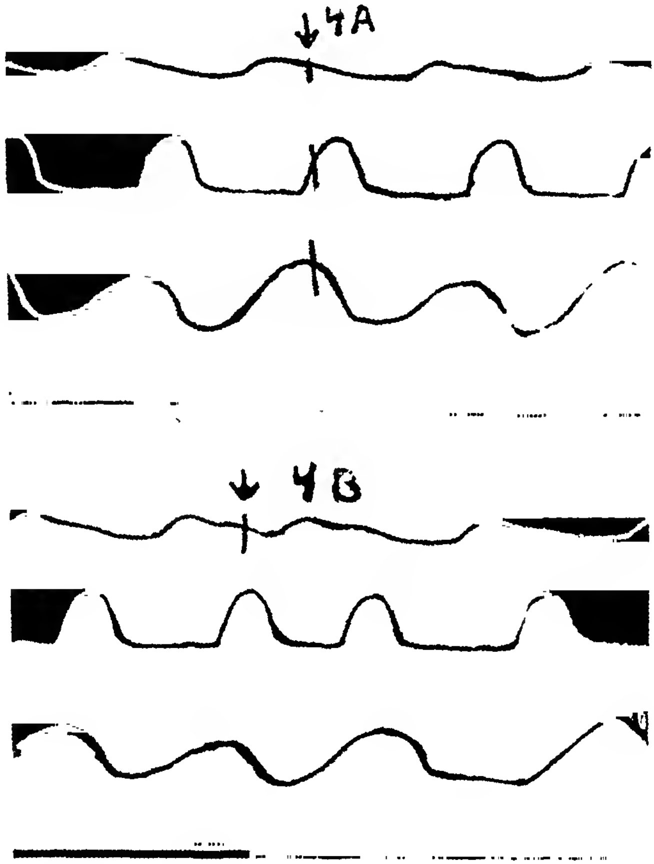

Fig. 4.—Heart rate, 21 per minute. Tracings and coil same as in Fig. 1.

A, A stimulus applied in the middle of the cycle had no effect. The relative refractory period of the sinus in this tortoise was longer than usual.

B, A stimulus of the same strength as in *A* applied slightly later in the cycle induced an extra contraction of the sinus which was carried to the auricles and ventricles. The pause that followed was longer than normal.

The increased height of the "postcompensatory" contraction as applied to the ventricle was well discussed by Cushny,[5] who compares it to a staircase phenomenon. In our work it has occurred after sinus stimulation. Fig. 3*A* exhibits it in the ventricle and to some extent in the auricle, while Fig. 1 *A* and *C* shows it occurring in the sinus even though the pause following the extrasystole was either longer or shorter than normal. Fig. 3*A* is of further interest because the compensatory pause in the auricles and in the ventricles was not preceded by an extrasystole, and therefore the factors leading to the increased height of the "postcompensatory" contraction must have their genesis associated only with the rest period.

DISCUSSION

Among the great number of papers reviewed, those dealing with electrical stimulation of the heart[6-8] have presented a mass of material and illustrations that bear on our results, yet they do not show records of sinal contraction. The original figures of Marey[9] showing the compensatory pause of the ventricle are still the classical illustrations in this field. Schultz[10] has studied records of the isolated sinus and auricles. With these researches as a background, Lewis[3] discussed and showed diagrammatically the condition of the sinus, auricles, and ventricles during the extra discharges and other irregularities of the pacemaker. Our records taken simultaneously from the sinus, auricles, and ventricles confirm and extend the diagrams of Lewis[3] and others.[11-13]

All the records shown (Figs. 1 to 4) were obtained several times so that we feel that the results illustrated by these figures are not incidental to the technique but represent the actual activity of the sinus. Also we have obtained at room temperature reproductions of all the records obtained with cooled preparations, thus demonstrating that the results obtained with cooled hearts were not bizarre due to the cooling of the heart as Cushny[5] long ago warned against.

One of the most frequent questions asked by students is what happens to the rhythmic discharge of the sinus following an extra stimulus and systole of the sinus? We have answered this by careful measurements of time relations and can therefore say that the time in the cycle when the stimulus is applied usually determines the length of the pause preceding the next sinus discharge. The next most important factor is the condition of the tortoise. All of the records illustrated as well as the data in Table I were taken from fresh preparations in which relatively weak stimuli gave satisfactory results. In addition, many records were taken from tortoises in poor condition; that is, several hours after pithing, preparing, and use. These data showed the refractory and relative refractory periods were longer than normal and that an extrasystole placed as early in the cycle as the sinus would permit was almost always followed by a longer pause than normal.

Thus it is obvious that the pause following an extra stimulus to the sinus, although variable, is predictable in length and probably depends somewhat upon the physiologic condition of the cells responsible for the discharge but mostly on the time of stimulation. With these factors in mind the stimulus may be placed so as to give an extrasystole and pause which will show a fairly consistent pattern when repeated records are taken from the same tortoise.

SUMMARY

Graphic records of the contractions of the sinus venosus of turtles were obtained simultaneously with contractions of the auricles and ventricles.

An electrical stimulus applied during the refractory period of the sinus will not cause an extrasystole, but the rhythm may be disturbed.

Electrical stimuli applied to the sinus during its quiescent period caused a contraction which may or may not be carried in turn to the auricles and ventricles.

The pause in the sinus (returning cycle) following an extra or induced contraction of the sinus may be shorter, longer, or equal to normal. The factors determining the length of this pause are governed to some extent by the physiologic condition or property of the cells in the sinus but mostly by the time in the cycle when the extrasystole is induced. With these factors in mind, the sinus of any tortoise will exhibit somewhat predetermined temporal discharges following electrical stimulation. This was indicated by the fact that an extrasystole occurring in early diastole was usually followed by a pause of shorter duration than normal, while one occurring near the end of the cycle was usually followed by a pause of longer duration than normal.

The height of the next contraction of the sinus after an extrasystole of the sinus may be higher than normal even though the pause preceding it was shorter than normal.

The strength of the stimulus may be changed from threshold to considerably above threshold without affecting the results.

float is confined to a cylinder (*D*) through which a constant flow of liquid (*E*) can be maintained by gravity.

Dimensions of the assembly are arbitrary and within limits can be varied considerably, especially in length. Considerable use has been made of one suitable for dialyzing 25 c.c. of material. The outside dimensions of the cylindrical plug (*C*) are 1.91 × 21.5 cm., and the diameter of the dialysis membrane is listed as 29/32 inch inflated diameter by the manufacturer. In operation the thickness of the material to be dialyzed is about 0.16 cm., and each cubic centimeter is exposed to a surface area of approximately 6.0 sq. cm.

To illustrate (curve on Fig. 1) the characteristics of the apparatus with the above dimensions 25 c.c. of a 2 per cent solution of oxalic acid were dialyzed against water. The water flow through the cylinder D was 100 c.c. per minute. At the end of fifteen minutes half of the oxalate had dialyzed through the membrane, most of it had disappeared within the hour, and only small amounts remained at the end of three hours. Without the glass plug approximately 10 per cent will remain at the end of two hours. If the water flow through the cylinder is reduced to 50 c.c. per minute or increased to 600 c.c. there is no appreciable change in the dialysis rate.

ROUTINE ANALYSIS OF URINARY CALCULI*

A Rapid, Simple Method Using Spot Tests

Julius H. Winer,† M.D., and Marjorie R. Mattice, M.S.
New York, N. Y.

URINARY stone analysis is an important factor in determining the etiology of a stone and subsequent management of the patient. The common "systems" of stone analysis have often been regarded with misgivings since they appear to be too complicated, time-consuming, or otherwise unsatisfactory from the standpoint of the urologist. We have, therefore, compiled simple chemical tests whereby a dependable analysis may be made in the ordinary office laboratory in a few minutes by a worker without special training. A further advantage is that several calculi may be examined simultaneously without additional effort.

Reagents.—The appended list of reagents includes several which are not essential, since alternative methods are given to allow for individual choice. If these solutions are kept in dropper-type bottles, their use is facilitated, since only minute amounts are needed for testing.

Uric acid reagent: Consult textbooks for the preparation of the Benedict or Folin-Denis reagents used for urine and blood uric acid determinations.

*From the Department of Urology and the Division of Pathological Chemistry, Department of Medicine, New York Post-Graduate Medical School of Columbia University.
Received for publication, July 10, 1942.
†Now Lieutenant Medical Corps, U. S. Army.

Sodium carbonate: 20 per cent solution.

Ammonium molybdate: Several different solutions may be employed but that suggested by Seifter and Trattner[10] is excellent. Dissolve 3.5 Gm. of ammonium molybdate in 75 c.c. of water and pour into 25 c.c. of concentrated nitric acid.

Manganese dioxide: A heavy, fine, black powder, MnO_2.

Resorcinol or resorcin: Pure white needlelike crystals $C_6H_4(OH)_2$.

Hydrochloric acid: 10 per cent solution (concentrated acid diluted ten times).

Sulfuric acid: Concentrated H_2SO_4.

Sodium hydroxide: 20 or 25 per cent solution.

Ammonium hydroxide: 28 per cent (concentrated).

Reagent "M": Dissolve 1 mg. of p-nitrobenzene-azoresorcinol in 100 c.c. of normal sodium hydroxide (Eastman).

Nessler's solution: Consult textbooks for the preparation of the Bock-Benedict or Folin formula for blood analyses.

Sodium cyanide: Prepare a 5 per cent solution and preserve with 1 c.c. of 28 per cent ammonium hydroxide per 500 c.c. of solution.

Sodium nitrite: A fresh solution, 0.1 per cent, should be prepared once a week, although it often keeps much longer.

Sodium nitroprusside (nitroferricyanide): Prepare a 5 per cent solution and discard when it shows signs of fading. Protect from light.

Reagent "S": Dissolve 100 mg. of N-(1-naphthyl)ethylenediamine dihydrochloride (La Motte Chemical Products Company) in 100 c.c. of water. Store in an amber bottle.

Reagent "S" (alternative): Dilute 1 c.c. of dimethyl-α-naphthylamine (Eastman) in 250 c.c. of 95 per cent alcohol.

Nitric acid: Concentrated (unnecessary unless murexide supplementary test is employed).

Procedures.—The general scheme of analysis is presented in tabulated form. The calculus should be split so as to reveal different structures within, and the core or nucleus should be distinguished from the various layers by separate analysis. For full evaluation of the results the relative sensitivity of the various tests should be taken into account. The findings depend largely on the methods used to detect possible constituents of the stone. Since the calculus is constantly bathed in urine during its formation, traces of every substance found therein would be discovered in the stone if sufficiently delicate procedures were employed. The purpose of our scheme of analysis is to reveal the chief components of the stone, the minor constituents being of research rather than practical importance insofar as the present state of knowledge is concerned.

When the reagents for the Benedict-Theis method of determining serum *phosphate* are used on urinary calculi, they give a "positive" reaction with a majority of stones, including some thought to be "pure" cystine. It is, therefore, impractical to employ such a test.

The murexide test for *uric acid* is less sensitive than the recommended reagents, although it must be stressed that only a deep blue color should be re-

TABLE I

SCHEME OF ANALYSIS OF URINARY CALCULI

Chemical Group	*Reagents Added*	*Results*
1. Urates	Pulverized stone 1 drop Na_2CO_3 2 drops uric acid reagent	Prompt deep *blue* color (pale blue is negative)
2. Phosphates*	Pulverized stone 4-5 drops ammonium molybdate solution (need excess of reagent)	Warm over flame to get distinct *yellow precipitate,* $(NH_4)_3PO_4 \cdot 12\ MoO_3$
3. Oxalates	Pulverized stone Pinch of resorcinol 1 drop conc. H_2SO_4 Mix	Slow development of dull *bluish-green* color (Higgins and Mendenhall[5])
4. Oxalates	Pulverized stone 2-3 drops HCl. If no effervescence, add pinch of MnO_2. Do not mix	Tiny *bubbles of gas* "explosively" released from bottom
5. Carbonates	Relatively large sample of pulverized stone 8-10 drops HCl	*Effervescence*
Take up acid extract from *5* in aspirating pipette the tip of which is lightly plugged with cotton. Remove cotton by seizing projecting wisp and divide "filtrate" into three aliquots for *6, 7,* and *8.*		
6. Calcium*	Acid extract 2-3 drops NaOH	Fine *white* precipitate or film from oxalate stones; dense precipitate from phosphate stones
7. Magnesium	Acid extract 2-3 drops NaOH 2-3 drops reagent "M"	Reddish-purple reagent slowly becomes definitely *blue* (precipitate forms)
8. NH_4 group	Acid extract 2-3 drops NaOH 2-3 drops Nessler's solution *Alternative:* Pulverized stone 2-3 drops Nessler's solution	*Yellowish-orange* precipitate
9. Sulfonamides	Pulverized stone 2 drops HCl (wait 30 seconds) 2 drops $NaNO_2$ (wait 30-60 seconds) 2-3 drops reagent "S"	*Brownish-pink* to *magenta*
10. Sulfonamides	Pulverized stone 8-10 drops HCl Stir with broken piece of match stick or wooden applicator Let stick remain *in situ* for several minutes	Lignin in wood becomes *yellow* or *orange.* Use stick for "writing" on paper towel or newspaper. The colorless acid extract turns *yellow* on lignin-containing paper but not on rag stock (Halley[3])
11. Cystine	Pulverized stone 1 drop NH_4OH 1 drop NaCN (wait 5 minutes) 2-3 drops sodium nitroprusside	*Beet-red* color; on standing may fade to orange red

*Use a microscope slide for these tests, spot plate for the others. The artist's type is more satisfactory than the regular chemist's spot plate.

garded as "positive" (test 1). The murexide test, however, is much more useful and informative as shown later.

Nessler's solution (test 8) will detect smaller amounts of *ammonia* than will pink litmus paper when exposed to the gas released by treatment of an acidified extract of the calculus with sodium hydroxide.

The Marshall reagents will find smaller amounts of *sulfonamides* than will the lignin test of Halley. A relatively large sample of stone should be used for the latter procedure; even then the presence of an appreciable quantity of sulfonamide may not be detected.

Suitable tests for *oxalate* are not as sensitive or as specific as one might wish. In the experience of one of us (M. R. M.) the conversion of oxalate to carbonate by manganese dioxide has proved highly satisfactory (test 4). When only a minute fragment is available, oxalates can be found by using a narrow test tube and 5 to 10 drops of acid, and watching carefully with a magnifying lens for the ejection of a few bubbles of gas on addition of the black powder. This test for oxalates is not applicable to carbonate stones until all carbon dioxide has been removed from an acid extract by boiling. The solution must be cool before the manganese dioxide is added. However, we have rarely encountered carbonate in interfering amounts in oxalate stones, although Kamlet[5] reports finding carbonate in 12 out of 88 oxalate stones. With moderate-sized samples the test is easily carried out on a white or clear-glass spot plate if the black powder is not mixed after it falls upon the particles of stone. After a moment's hesitation tiny bubbles of gas are shot out like rockets. The effervescence seen after contact of hydrochloric acid with carbonate is different; the powdered stone is buoyed up by the immediate formation of many very fine bubbles of carbon dioxide. The Higgins-Mendenhall[4] test for oxalates (test 3), while specific and simple to perform, produces a poor color and that rather slowly, and requires a fairly generous test sample for easy recognition of oxalates.

Physical Characteristics.—Instances occur where the stone is minute or only a small part of it is available for study, necessitating the use of a few selected tests dependent on the examiner's ingenuity. Fortunately, the appearance of a stone generally gives a clue to its composition.

Uric acid often occurs as multiple, smooth, round pebbles, which are devoid of luster and vary in size from a few millimeters to 30 mm. or more in diameter. Single stones frequently have a bumpy or eruptive type of surface, resembling miniature volcanic craters. Uric acid stones are always definitely yellow, but this color may not be noted until the stone is crushed.

Phosphate and *carbonate* stones occur as compact balls (often several centimeters in diameter) or as large friable masses assuming the shape of the cavity were found; these are clay or chalk-like. Rarely, triple phosphate stones ($MgNH_4PO_4$) assume porous, coral-like formations, which suggest calcium oxalate except for their whiteness.

Oxalate stones show considerable variety in form. Irregular, light-colored fragments may exhibit elaborate crystalline structures with sharp projecting blades. Oxalate stones are conspicuous for their crystalline glint or smooth luster. The dark-brown type is very compact and may take a grape-seed or berry-like form, which should be differentiated from the prostatic corpora amylacea. If the rounded contours are larger, like a bunch of grapes, the calculi may be described as botryoidal. Although the berry and compact stratified forms are dark brown, crushing produces a light-colored powder. Mammillated

oxalate stones occur, although the nipplelike structure is rarer than a prickly surface, resembling the "eruptive" type of uric acid calculus. Buff-colored or brown stones may be covered with a fine coral-like excrescence. Occasionally, the whole structure is loose and porous.

Cystine stones occur largely as pale yellow or white granules upon which the pestle seems to skid as it crushes the calculus. Multiple stones may develop in the form of uric acid pebbles, except that they are usually much smaller, many hardly reaching 1 mm. in diameter. Such stones possess a faint waxy luster and are brownish in color which distinguishes them from the yellow uric acid pebbles. Another form of cystine stone resembles calcium oxalate on casual inspection since it presents a crystalline surface.

The *sulfonamides* may be deposited on the surface of uric acid without obvious layering or may be mingled with phosphate and carbonate in a putty-like mass. There is nothing in the physical appearance of the stone to suggest the presence of sulfonamides. It is yet to be determined whether or not "pure" sulfonamide calculi will occur.

It is important to analyze prominent layers of calculi when possible. Although uric acid stones often are "pure," they frequently pick up a thick crust or coating of different nature, usually phosphates unless sulfonamides are available. Phosphates do not, as a rule, deposit as a visible crust on oxalate stones but occur throughout the calculus. Instances are seen where uric acid encircles an oxalate nucleus several millimeters in diameter and then is thickly encased in magnesium ammonium phosphate and calcium carbonate.

Supplementary Tests.—Tests other than those described in the table may be desired by the technician for guidance or for checking purposes. The following tests are valuable in that they furnish a lead as to the presence of substances other than those sought.

Murexide Test.—When a sample of pulverized stone is treated with several drops of concentrated nitric acid and carefully evaporated to dryness, then subjected to 2-3 drops of ammonia water, the following may be observed:

Uric acid— deep yellow to orange-red or crimson becoming more purplish with ammonium hydroxide (bluish violet with sodium hydroxide).
Xanthine— greenish-yellow turning to orange with ammonium hydroxide becoming reddish on warming (deep orange-red with sodium hydroxide).
Protein— pale yellow turning to orange.
Sulfonamides—yellow turning to mahogany brown.

It should be emphasized that the murexide test for uric acid usually is carried out in an evaporating dish on a water bath, but this may not provide a sufficiently high temperature for the xanthine reaction. It is very easy to miss xanthine in urinary calculi.

According to commonly used "systems" of stone analysis, no gas is evolved when concentrated nitric acid is added to a pulverized uric acid calculus, whereas effervescence occurs in the presence of ammonium urate. Domanski[1] emphasizes this point and further states that uric acid is not appreciably soluble in nitric acid, although urates dissolve readily. In our experience both uric acid and urates are soluble under these conditions. Uric acid, whether reagent pure, re-

covered from a lateritious deposit or obtained in calcareous form, reacts with concentrated nitric acid so as to release a continuous stream of bubbles until the powder is no longer visible. In the case of stones, the effervescence is quite frothy whereas it is quieter and confined to a swirling motion within the fluid when pure uric acid is tested, but this may be due solely to the fact that the reagent grade acid exists in a more finely divided form than does the crudely ground calculus. All stones giving a positive murexide test have shown this gas formation whether ammonium urate was present or not.

In this connection a further point needs clarification. The standard method for testing for the ammonium radical in urinary stones involves the addition of strong alkali for the release of ammonia gas and its detection by wet pink litmus paper or filter paper treated with Nessler's solution. Domanski found that ammonia was not obtained from ammonium urate by this process. We have had no difficulty in distinguishing between ammonium urate and uric acid stones by the method described in this paper (test 8). However, ammonium urate stones appear to be relatively rare—which may be less fact than failure to discover the ammonium radical.

Ashing Process.—Another helpful procedure is to ash a sample of the stone in a porcelain crucible. This is a desirable preliminary to the test for phosphates given in the table (test 2) but is not essential. It is difficult to evaluate the odor of the heated stone except in the case of cystine. This penetrating odor, once experienced, is never forgotten. It follows the first curl of smoke and diminishes in intensity with increased heat. Both cystine and urate stones blacken rapidly, the former burning "clean" and the latter with advancing greasy brown rings up the crucible; both leave the crucible empty. The residue from phosphate and oxalate stones is of about the same bulk as the original sample. The phosphates rarely give a white ash even after long and hard heating. With oxalates the ash is more nearly white and effervesces if acid is added as in testing for phosphorus since oxalate is converted into carbonate by heating. This effervescence is not to be confused with spattering obtained on adding a fluid to the hot ash. Sulfonamides melt and form a black tarry mass which is resistant to ashing. It can be seen, then, that the response to heating may furnish valuable clues as to the composition of a calculus.

SUMMARY

1. A scheme of urolith analysis is presented which is simple, rapid, and dependable.

2. A number of calculi or separate layers can be analyzed simultaneously with the simple equipment required.

3. The physical characteristics of urinary stones and supplementary means for testing their composition are discussed.

Appreciation is expressed to Dr. Joseph A. Hyams for his stimulating interest in this investigation.

A CRITICAL STUDY OF THE CARR-PRICE REACTION FOR THE DETERMINATION OF β-CAROTENE AND VITAMIN A IN BIOLOGICAL MATERIALS*

Margaret Kaser, Ph.D., and Jakob A. Stekol, D.Sc., Nashville, Tenn.

SEVERAL methods based on the Carr-Price[1] reaction for the determination of β-carotene and vitamin A in biological materials have been described and widely applied to nutritional studies.[3, 7-9, 11, 13] The limitations of the reaction have been pointed out on several occasions[3, 7] and summarized recently[12] with the conclusion that under properly controlled conditions the antimony trichloride reaction with β-carotene and vitamin A is suitable for some studies, although spectrophotometric and biological assays give more reliable results. Sakamoto[14] found good agreement between values for β-carotene and vitamin A obtained by polarimetric and colorimetric methods. Embree[4] finds that the measurement of the color produced by antimony trichloride in the presence of vitamin A by the use of the photoelectric colorimeter is almost as exact as that given by the spectrophotometer. Salter,[15] on the other hand, in a recent review stated that the methods for vitamin A based on the Carr-Price reaction are too erratic for routine use.

We have had occasion in this laboratory to use the Carr-Price reaction for the analysis of a large number of samples of blood plasma or serum, vitamin concentrates, and rat tissues. In view of the recent criticism of the reaction, it appeared important to establish the validity of the results obtained by such a procedure. Therefore, the present work was undertaken.

EXPERIMENTAL

Two modifications of the Carr-Price reaction, both of which involve the use of the Evelyn colorimeter, have been studied. One is the micromethod described in detail by May, Blackfan, McCreary, and Allen,[10] and the other is

*From the Department of Biochemistry, Vanderbilt University Medical School, Nashville.
Received for publication, July 13, 1942.

the macroprocedure outlined briefly by Lewis, Bodansky, and Haig.[9] The two methods were compared for the reproducibility of results on different and on the same samples of blood plasma. Since the macroprocedure was found satisfactory in our hands, we shall describe it in detail. Recovery studies of crystalline β-carotene and vitamin A employing the macroprocedure were also made. Although Embree[4] found that serious loss of vitamin A potency results from exposure of solutions of vitamin A in clear glass test tubes to ultraviolet light for four to five and a half hours, we used throughout only clear glass glassware. Since the average time necessary to complete the determinations was an hour or less, the excellent recoveries obtained indicate that the destructive influence of ultraviolet light under the conditions used was not in evidence. However, when a large number of samples are run at the same time, requiring several hours for the completion of the determinations, Embree's[4] suggestion to use amber glassware to prevent the destruction of vitamin A by ultraviolet light becomes of practical importance, particularly in the case of samples of low vitamin A potency.

MACROPROCEDURE. BLOOD PLASMA OR SERUM

Five milliliters of 95 per cent alcohol and 8 ml. of petroleum ether (B.P. 35° to 75° C.) are added to 3 to 5 ml. samples of blood plasma or serum, and the tubes are shaken on a mechanical shaker for ten minutes. After centrifuging two or three minutes at 1,300 r.p.m., 6 ml. of the petroleum ether layer are transferred to a previously calibrated colorimeter tube, and the carotene reading is taken with filter 440. The Evelyn tube is immersed in a water bath at about 65° C. and is connected to a water pump. Evaporation is complete in four or five minutes. Prolonging the time of evaporation to ten or fifteen minutes was found to lower the vitamin A values by about 10 per cent. The residue is dissolved in 0.6 ml. of chloroform, and with the tube inserted in the colorimeter, 5.4 ml. of 25 per cent antimony chloride in chloroform are added as quickly as possible. The minimum galvanometer reading with filter 620 is taken within three seconds before the color developed begins to fade.

The carotene values are calculated with the constants of Koehn and Sherman,[7] and for vitamin A we have used the formula of Dann and Evelyn[3] and the factor of 2,100 given by Holmes and Corbet[5] for converting $E\,\frac{1\%}{1\text{ cm.}}$ (328 mμ) to international units.

$$\frac{L_{440} \times 2.65 \times 6 \times 100}{\frac{3}{4} \times \text{ml. of sample}} = \text{Micrograms of carotene per 100 ml.}$$

$$\left[\frac{L_{620}}{\frac{3}{4} \times \text{ml. of sample}} - \frac{0.14\ L_{440}}{\frac{3}{4} \times \text{ml. of sample}}\right] \times 52.5 \times \frac{6}{100} \times 0.41 \times 2{,}100 = \text{I. U. vitamin A per 100 ml.}$$

RAT LIVER

One gram samples of liver are heated with 5 ml. of saturated potassium hydroxide in 95 per cent alcohol at 75°-80° C. for forty-five minutes with occasional shaking. After cooling, the digests are made up to 10 ml. with water.

For liver samples containing about 100 to 1,000 international units per gram; an aliquot of 0.2 ml. is taken for analysis. The sample is diluted to about 5 ml. with water and from this point the determination is carried out in the same way as was described for blood plasma.

Applying this procedure to the livers of rats maintained on diets of various nutritional qualities, we obtained concordant results with satisfactory reproducibility.[14]

DISCUSSION

Table I shows data obtained by the microprocedure of May, Blackfan, McCreary, and Allen[10] and the procedure described above. The objective was to check the reproducibility of the values obtained by both procedures on different samples of blood plasma. Table II illustrates the analytical values obtained by both procedures on the same samples. It will be seen from the data presented that the macroprocedure described above gives consistently better and more reproducible values than the microprocedure. We believe that this difference in the performance of the procedures is not due to any dif-

ference in the basic principle employed, but to the difficulty in carrying out all the steps involved in a sufficiently short time by the microprocedure as is essential to the accuracy of the reaction.

Table III indicates that no significant increase in the vitamin A resulted after a preliminary saponification of 3 ml. samples of plasma in alcoholic potassium hydroxide for twenty minutes. It appears that most of the vitamin in normal human plasma exists in the free form, as has been suggested previously.[2]

TABLE III

EFFECT OF SAPONIFICATION ON THE β-CAROTENE AND VITAMIN A VALUES OF NORMAL HUMAN BLOOD PLASMA

*The weights of crystalline vitamin taken were converted to international units by means of the relationship of 3 I. U. per microgram given by Holmes and Corbet.[5]

Recoveries of carotene and vitamin A were made on separate solutions of known concentration. The average deviation from the theoretical values, as calculated from the figures above, was +1.6 per cent for carotene and −1.9 per cent for vitamin A.

Tables IV and V show data illustrating the recovery of crystalline β-carotene and vitamin A from petroleum ether, either separately or when mixed in various proportions. As will be seen, the procedure outlined above gives excellent recoveries with reasonable experimental errors. In Table VI are presented data for the recovery of β-carotene and vitamin A from normal human plasma. Again the recoveries were sufficiently good to warrant the use of the procedure for routine use.

TABLE V

RECOVERY OF MIXTURES OF CRYSTALLINE β-CAROTENE AND VITAMIN A FROM PETROLEUM ETHER

SERIES	CAROTENE ADDED µG	CAROTENE FOUND µG	VITAMIN A ADDED µG	VITAMIN A ADDED I. U.*	VITAMIN A FOUND I. U.
I	0.708	0.728	0.421	1.263	1.434
	2.123	2.103	0.421	1.263	1.341
	3.540	3.557	0.421	1.263	1.170
	4.957	4.692	0.421	1.263	1.218
	6.490	6.201	0.421	1.263	1.110
II	0.708	0.863	3.507	10.521	10.680
	2.123	2.103	3.507	10.521	10.377
	3.540	3.499	3.507	10.521	10.560
	4.957	4.723	3.507	10.521	10.347
	6.490	6.237	3.507	10.521	10.635

*The weights of crystalline vitamin taken were converted to international units by means of the relationship of 3 I. U. per microgram given by Holmes and Corbet.[5]

The average deviation from the theoretical values in series I was −0.2 per cent for carotene and +2.2 per cent for vitamin A; in series II, for carotene it was +10.8 per cent and for vitamin A −0.6 per cent.

TABLE VI

RECOVERY OF CRYSTALLINE β-CAROTENE AND VITAMIN A ADDED TO BLOOD PLASMA

PLASMA LEVELS		CAROTENE		VITAMIN A*		TOTAL RECOVERED

*The weights of crystalline vitamin taken were converted to international units by means of the relationship of 3 I. U. per microgram given by Holmes and Corbet.[5]

Petroleum ether solutions of β-carotene and vitamin A of known concentration were added to normal human blood plasma in which the concentrations of carotene and vitamin A were previously determined.

SUMMARY

The applicability of the Carr-Price reaction to the analysis of biological materials has been critically re-examined using the Evelyn photoelectric colorimeter. Excellent recoveries of crystalline β-carotene and vitamin A were obtained with reproducible results. The macroprocedure described was found satisfactory for routine analysis of blood plasma or serum. Preliminary saponification of plasma or serum was found to have no significant effect on the vitamin A or carotene concentrations in normal human plasma. Recent criticisms directed against the Carr-Price reaction as the basis for the quantitative determination of vitamin A and β-carotene in biological materials should take into account the carefully specified conditions which are essential to the successful application of this reaction.

The studies referred to herein were conducted under the auspices of the International Health Division of the Rockefeller Foundation of New York City by the nutrition units of the Departments of Biochemistry and Medicine, Vanderbilt University School of Medicine, Nashville, Tenn.

PROTHROMBIN STUDIES USING RUSSELL VIPER VENOM

IV. Relation Between Prothrombin Clotting Time and Plasma Fibrinogen Concentration

Robert C. Page, M.D., Edwin J. de Beer, Ph.D., and Z. Bercovitz, M.D.
New York, N. Y.

THE clinical interpretation of laboratory tests must be based on a knowledge of factors that may cause a variation in the test. The increasing use of the prothrombin clotting time test in studying bleeding and hemorrhage brings up the question of the relation of prothrombin clotting time to the blood concentration of other factors involved in the coagulation mechanism (calcium, thromboplastin, fibrinogen, etc.).

The study reported here consisted of obtaining blood from healthy adults and from patients with chronic ulcerative colitis or miscellaneous gastrointestinal diseases and determining the prothrombin clotting time and the fibrinogen content of the plasma.

METHOD OF STUDY

Blood of healthy normal adults and of patients attending an outpatient clinic was obtained. Most of the blood was obtained in the afternoon so these were mainly postprandial specimens. Blood for determination of the prothrombin clotting time and fibrinogen content was drawn at the same time.

The method employed was Quick's procedure[1] modified by using Russell viper venom instead of brain thromboplastin.[2-4] Four and one-half cubic centimeters of venous blood were drawn into a dry syringe and mixed with 10 mg. of potassium oxalate in a centrifuge tube. The blood was centrifuged at 1,500 r.p.m. for five minutes, and the oxalated plasma was drawn off. The test was performed within two hours after withdrawal of the blood; if hemolysis was present, the sample was discarded. The test was performed as follows: 0.2 c.c. of oxalated plasma was pipetted into a small test tube (75 by 10 mm.), and 0.2 c.c. of Russell viper venom,* 1:10,000 solution, was added. Calcium chloride solution (1.11 Gm. calcium chloride per 100 c.c.), 0.2 c.c., was then added, and the stop watch immediately started. The tube was agitated for from ten to fifteen seconds and tilted until separate discrete fibrin particles could be seen. The prothrombin clotting time in normal individuals using Russell viper venom has been found to be 20.76 seconds $\pm$ 2.32 seconds[3] and 19.5 seconds $\pm$ 2.9 seconds.[5]

The method used for the fibrinogen content of blood plasma was a combination of the methods of Howe[6] and Wu[7] and Koch and McMeekin[8] as

adopted in the Biochemical Laboratories of the Philadelphia General Hospital. One cubic centimeter of oxalated plasma was diluted with 48 c.c. of physiologic saline. One cubic centimeter of calcium chloride was then added and the mixture was allowed to stand for thirty minutes. The clot was removed, dried, and placed in an ignition tube with 1 c.c. of acid digestion mixture. Five drops of caprylic alcohol were added to prevent foaming. The mixture was boiled vigorously and when white fumes appeared, superoxol (30 per cent H_2O_2) was added to clear the solution (about 0.5 c.c.). The solution was again heated vigorously and then cooled. Distilled water was added to make a total volume of 35 c.c. Fifteen cubic centimeters of Nessler's solution were then added, the solution was centrifuged, and the supernatant fluid was matched against standards containing from 0.6 to 1.0 mg. of nitrogen. The normal range for plasma fibrinogen with this procedure is 0.2 to 0.4 Gm. per 100 c.c.

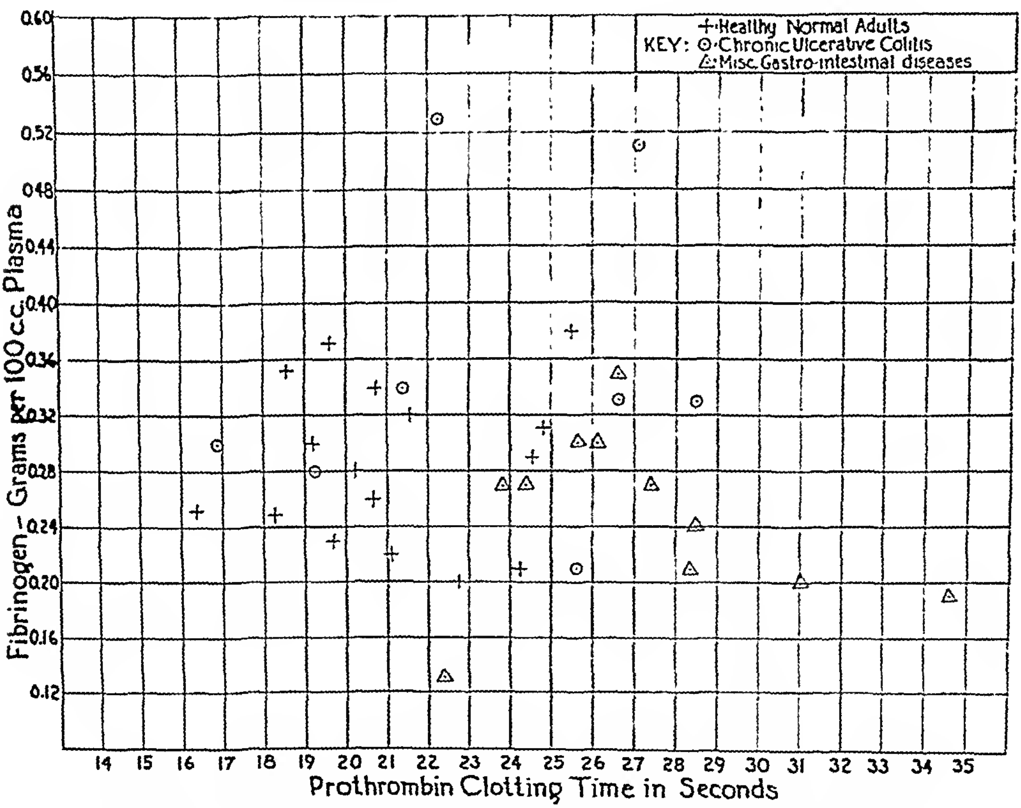

Fig. 1.—Chart showing relation between prothrombin clotting time and plasma fibrinogen in normal adults and in patients with gastrointestinal disorders.

DISCUSSION OF RESULTS

The results are plotted in Fig. 1. It will be observed that the points are widely scattered, and there is little evidence of any trend except possibly that longer prothrombin clotting times are associated with lower concentrations of fibrinogen. This possibility was investigated by calculating the correlation coefficient which was found to be −0.145. Since this figure fails to exceed the tabular value of 0.3246 given by Fisher and Yates[9] for a probability of 0.05

which corresponds to 1 chance in 20, no correlation can be said to exist. Consequently, the prothrombin time in these data is independent of the amount of fibrinogen in the plasma. However, this does not exclude the possibility that in certain as yet unknown diseases a correlation between these two variables will be found.

SUMMARY AND CONCLUSIONS

No relationship was found to exist between the prothrombin clotting time and the concentration of fibrinogen in the plasma in normal subjects and in patients with a variety of gastrointestinal lesions.

PROTHROMBIN STUDIES USING RUSSELL VIPER VENOM

V. Interbatch Variations of Venom

Robert C. Page, M.D., and Edwin J. de Beer, Ph.D.
New York, N. Y.

Russell viper venom has been used for more than two years by us as a thromboplastic agent in a modified form of Quick's prothrombin test.[1] The modification consists in substituting Russell viper venom for brain thromboplastin. However, more information on the stability and uniformity of different batches of Russell viper venom is desirable when it is to be used in such a quantitative time relation test.

Other workers using Russell viper venom in this test have mentioned the subject of interbatch variations. Witts and Hobson[2] stated that different

Received for publication, July 23, 1942.

batches of Russell viper venom as purchased vary in coagulant power but that vials from the same batch are very constant. Crosbie and Scarborough[3] used two different batches of venom which did not differ appreciably in activity.

The object of the present study was twofold: (1) to learn how much variation existed between batches of Russell viper venom and (2) to determine if ageing had any effect on the potency of this type of preparation.

DESCRIPTION OF PREPARATION

The venom of the Russell viper (*Vipera russellii*) is collected by the usual methods employed at snake farms in India. The venom is then dried, sterilized, and standardized by comparing it with a sample of known potency on fowl and horse plasma. Following this the venom is packed in dry form in nitrogen-filled glass ampoules.

Venom in ampoules, of different batches, has been collected for the past four years and kept at room temperature so that when this study was begun samples from thirteen different batches were available and they varied in actual age up to five and one-half years.*

METHOD OF STUDY

Four essentially normal adults were selected, venous blood samples were obtained and prothrombin clotting times determined for each blood sample with each of the thirteen batches of venom.

The method employed was Quick's procedure[1] modified by using Russell viper venom instead of brain thromboplastin.[4, 5] Eighteen cubic centimeters of venous blood were drawn into a dry syringe and mixed with 40 mg. of potassium oxalate in a centrifuge tube. The blood was centrifuged at 1,500 r.p.m. for five minutes, the oxalated plasma was drawn off, and the tests were done immediately. The test on each batch was performed as follows: 0.2 c.c. of oxalated plasma was pipetted into a small test tube (75 by 10 mm.) and 0.2 c.c. of Russell viper venom,† 1:10,000, solution was added. Calcium chloride solution (1.11 Gm. calcium chloride per 100 c.c.), 0.2 c.c., was then added and the stop watch immediately started. The tube was agitated for from ten to fifteen seconds and tilted until separate discrete fibrin particles could be seen. The prothrombin clotting time in normal individuals using Russell viper venom has been found to be 20.76 seconds ± 2.32 seconds[5] and 19.5 seconds ± 2.9 seconds.[6] Each of the four subjects had essentially a normal prothrombin clotting time.

RESULTS OF STUDY

The results are given in Table I. In order to determine whether significant variations existed between batches and whether there was evidence of deterioration with age, the data were plotted as in Fig. 1. It will be observed that the mean prothrombin clotting times obtained with all batches regardless of age fell

*In the experiments, age of venom refers to elapsed time in days between the labeled "expiration date" and the date of the experiment. The venom actually was one year older than these figures indicate because the expiration date on the ampoule is one year in advance of the date on which the venom was placed in the ampoule.

*See first footnote on p. 913.

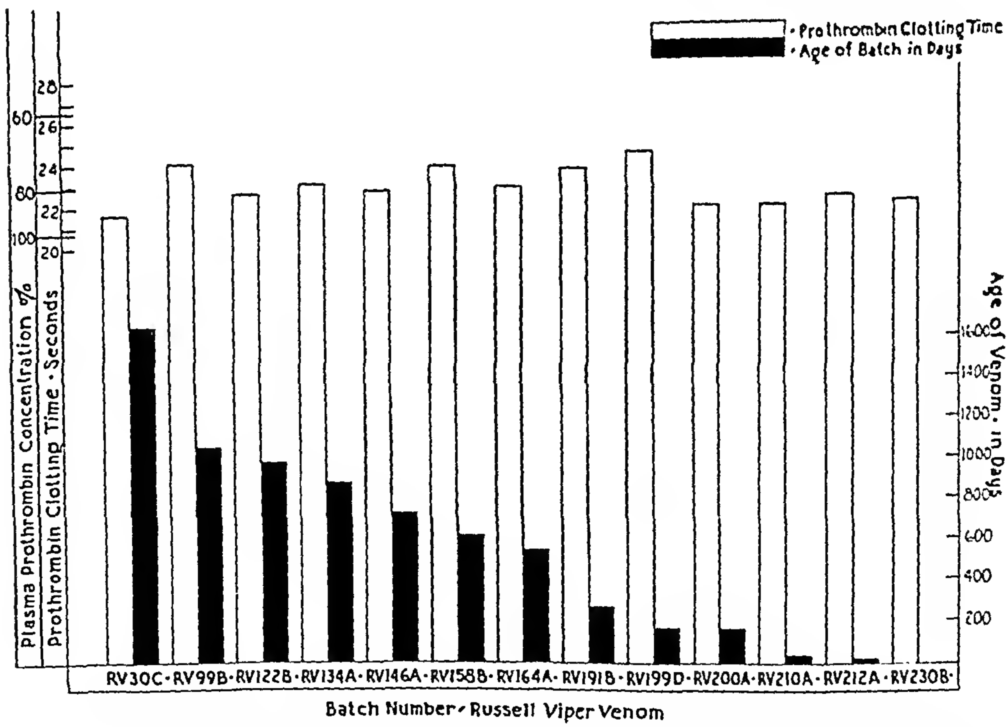

Fig. 1.—Bar graph showing the variations in prothrombin clotting time obtained with thirteen batches of Russell viper venom of different ages. Clear columns represent mean prothrombin clotting time; black columns represent age in days (time elapsed between expiration date and day of experiment) of the particular batch of venom.

within very narrow limits, roughly twenty-two to twenty-four seconds. Also, although the age of the oldest batch was 1,632 days (almost four and one-half years), its mean prothrombin time value (21.6 seconds) was almost the same as that obtained with the newest batch bearing an expiration date that would

not be reached until about eight months after this study and having a mean prothrombin clotting time of 22.3 seconds. It seems obvious, therefore, that as far as this study goes, age did not affect the potency of the preparation.

A statistical examination of the data, in which an analysis of variance was calculated, revealed that no significant variation between batches existed. F, the variance ratio, was 1.386 which, according to Snedecor's tables,[7] is not to be considered significant. If patients with prolonged prothrombin clotting times had been used in this study, greater variations would have been introduced, and the difficulty of detecting possible interbatch variations would have been increased.

SUMMARY AND CONCLUSIONS

1. Samples of Russell viper venom in nitrogen-filled ampoules were found to be stable over a period of at least five and one-half years.

2. Variations between thirteen different batches were not found to be significant.

We wish to express our appreciation for the assistance and cooperation of Dr. Louis Bauman in whose laboratory this work was carried out.

A SIMPLIFIED TECHNIQUE FOR MEASURING RENAL BLOOD FLOW AND TUBULAR EXCRETORY MASS

THOMAS FINDLEY, M.D., JOSEPH C. EDWARDS, M.D., ETTA CLINTON AND H. L. WHITE, M.D., ST. LOUIS, MO.

A RELIABLE simplification of Smith's original technique[1] for determining renal blood flow and tubular excretory mass would be highly desirable. We have previously reported[2] that the subcutaneous injection of diodrast and inulin can produce plasma concentrations suitable for clearance studies and that this method is very much more simple than that which depends upon constant intravenous infusion. Plasma iodine concentrations sufficiently high for the measurement of diodrast-Tm cannot be established in this way, however, so we have sought an empirical substitute. This report concerns an attempt to predict diodrast-Tm from the total quantity of diodrast excreted during the thirty minutes following a single intravenous injection of a standard dose. It appears that the percentage of diodrast excreted under these conditions is sufficiently proportional to diodrast-Tm to permit prediction of the latter from a line chart. The combination of these two modifications greatly simplifies the entire procedure and reduces the required number of blood and urine specimens by nearly one-half.

Plasma Diodrast and Inulin Clearance.—For subcutaneous use the 35 per cent diodrast solution* is irritating unless diluted about three times with saline. Inulin (Pfanstiehl, C. P.) must be thoroughly purified by boiling in water, filtering, and reprecipitating with alcohol three or four times until there is no visible residue on the filter paper; before each experiment the required amount is boiled again in 0.5 per cent saline sufficient to make a 25 per cent solution and injected while warm enough to remain in solution.

The optimal plasma concentration of diodrast is 1 to 5 mg. per 100 c.c.; of inulin, 5 to 15 mg. per 100 c.c. We originally reported that these may be achieved by the use of 0.2 c.c. diodrast and 0.2 Gm. of inulin per kilogram of body weight.[2] Extended experience has shown that amounts half this large are usually adequate, particularly in abnormal subjects. This means that a 70 kg. subject requires the subcutaneous injection of about 20 c.c. of diluted diodrast and 28 c.c. of 25 per cent inulin, but little discomfort arises since half of each solution is injected into the loose tissue of each axilla. Furthermore the injections of diodrast and inulin are separated by an interval of about forty-five minutes.

From the Departments of Medicine and Physiology, Washington University School of Medicine, and the St. Louis City Hospital, St. Louis, Mo.

Diodrast-iodine was determined by the method of White and Rolf[3] and inulin by a slight modification of that of Corcoran and Page.[2]

Diodrast-Tm Substitute.—In a study concerned with intravenous pyelography,[4] we have shown that normal subjects who received an intravenous injection of diodrast (0.2 to 0.6 c.c. kg. at a uniform rate during a five-minute period) excrete a relatively constant fraction of this dose during the next half hour but that the plasma iodine concentration falls somewhat below that required for Tm determination at the end of this time. Since at high plasma iodine concentrations the glomerular and tubular contributions to total urinary diodrast are approximately equal and since our abnormal subjects[5] have shown no marked disproportion between glomerular filtration rate and tubular excretory mass, it seemed likely that reductions in diodrast-Tm would be reflected by proportionate reductions in total diodrast excretion rates.

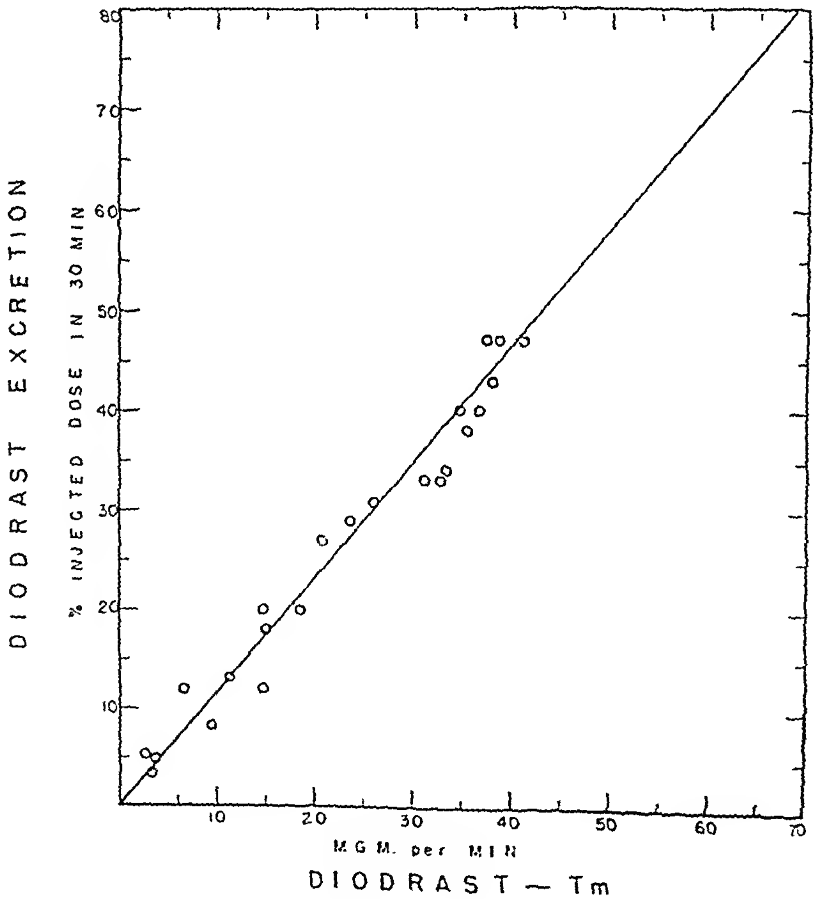

Chart 1.—Correlation between diodrast-Tm and the thirty-minute test.

Chart 1 shows results obtained on a series of normal subjects and patients with various renal disorders. The diodrast-Tm determinations were made by a slight modification of Smith's technique; most of them have been reported elsewhere.[5] Each point represents the average of at least three periods. Two or three days later each subject was given an intravenous injection of diodrast

(0.3 c.c. kg.) at a uniform rate during a five-minute period and the total amount excreted in the thirty minutes following completion of the injection determined. Expressed as a fraction of the injection dose, this value was plotted against diodrast-Tm. In Chart 1 it is not intended to minimize the occasional wide discrepancy at low Tm levels; the percentile difference is sometimes large but not, in our experience, larger than the fluctuations which have appeared in consecutive Tm periods obtained by the conventional infusion technique. This series is too small for statistical analysis, but it suggests that the error in predicting Tm from this line chart is less than ± 10 per cent.

Except for a few specially trained subjects, all of the half-hour urine collections were made by catheter and repeated bladder washings.

Combined Technique.—An indwelling catheter is applied to the fasting but hydrated subject, and a blood sample is obtained which serves as a blank for the diodrast and inulin determinations.

The subject lies on his back with his hands under his head. Under 1 per cent procaine anesthesia half of the inulin solution is injected into the subcutaneous tissues of each axilla at about the fifth interspace in the anterior axillary line. A 25 c.c. glass syringe is usually adequate and a three-inch 18-gauge needle is satisfactory. If the needle is fully inserted and slowly withdrawn during injection, no great rupture of tissue occurs. We have not massaged the areas after injection.

About forty-five minutes later the diluted diodrast is injected into the same places. This may cause momentary burning.

About fifteen minutes later the first blood sample (heparin) is obtained, the bladder is washed with saline, and clearance periods are established in the usual manner. Satisfactory plasma concentrations of diodrast and inulin exist for at least three hours.

The final blood sample is withdrawn after the last urine collection has been made. The quantity of undiluted diodrast necessary for Tm estimation (0.3 c.c. kg. in five minutes) is injected through the same needle and the bladder washed for the last time exactly thirty minutes after the end of the injection period. This sample is analyzed for diodrast only and completely replaces the minimum of three blood and three urine samples required by the intravenous technique.

It is of course essential that the catheter be draining freely and that the bladder be thoroughly washed. We have usually used five 20 c.c. portions of saline for this purpose, and all of these are added to the voided specimen before analysis.

One operator can easily examine two subjects simultaneously in this way.

DISCUSSION

Account must of course be taken of the diodrast contributed to the urine by the subcutaneous depots during the Tm period. The points in Chart 1 were obtained on diodrast-free subjects, but the combined technique described above requires that the thirty-minute test be performed on individuals whose

urine already contains diodrast coming from the axillary reservoirs. Failure to correct for the iodine from subcutaneous sources may increase the Tm estimate by 20 per cent.

Chart 2 presents the necessary correction factors; it is compiled from 195 plasma diodrast clearance periods in sixty-six subjects. Since the rate of diodrast excretion depends upon (a) the plasma concentration and (b) the plasma clearance, we have divided our renal blood flow data into five groups, depending upon the mean plasma diodrast concentration obtained during the clearance periods: 0 to 1, 1 to 2, 2 to 3, 3 to 4, and 4 to 5 mg. per 100 c.c. Each group is

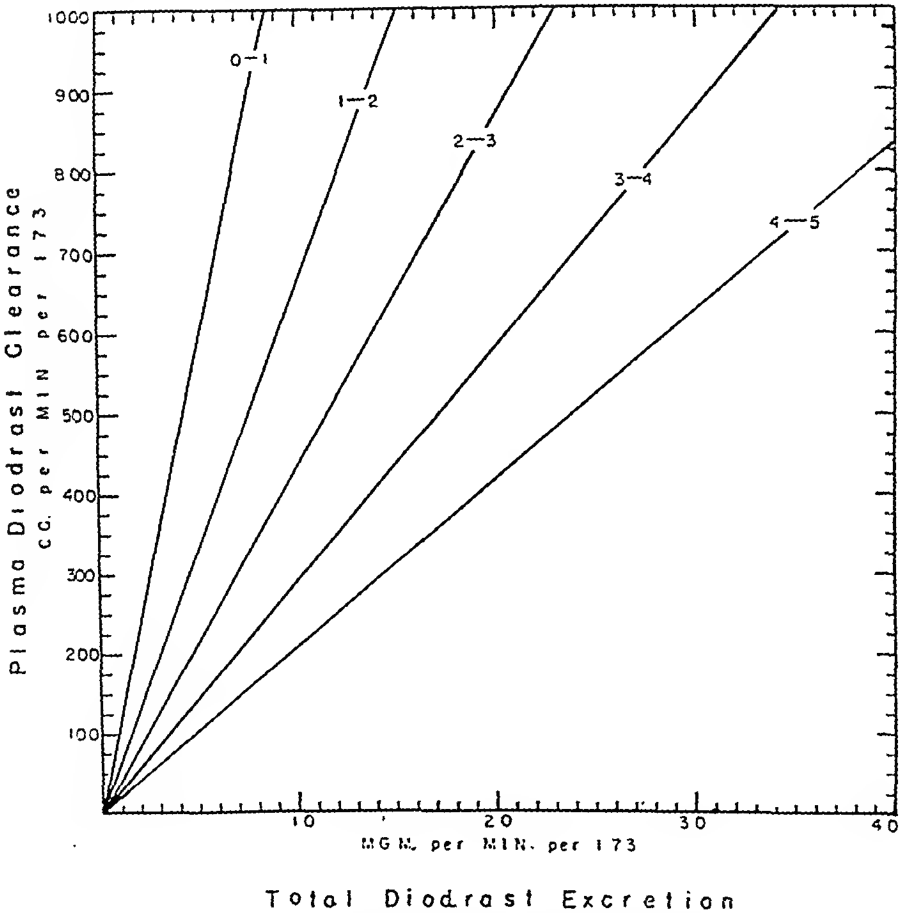

Chart 2.—Correction factors for diodrast-Tm prediction. The numbers on the slanting lines represent plasma diodrast-iodine concentrations in mg. per 100 c.c. From these values and the observed plasma clearances the quantity of diodrast coming from subcutaneous sources during the thirty-minute test may be predicted.

represented by a slanting line and contains plasma clearances plotted against total diodrast excretion rates. Assuming that the plasma clearance of subcutaneous diodrast is not altered by the intravenous injection, one may subtract the predicted total diodrast excretion rate for every minute elapsing between the last two bladder washings. This interval is, of course, variable, since it includes not only the five-minute injection period and the subsequent half-hour collection period, but also such time as may be necessary for obtaining the final

blood sample, changing syringes, etc. It has seemed better to make this correction than to attempt to wash the bladder twice in rapid succession. It is believed that these corrections for subcutaneous diodrast reduce possible errors in Tm estimation not dependent upon technical factors to considerably less than 5 per cent. These correction factors are probably a little too large, since renal diodrast extraction is more nearly complete at low than at high plasma concentrations.

CONCLUSION

A line chart is presented which permits prediction of diodrast-Tm from a single urine specimen. When this is combined with the subcutaneous method for determining renal plasma flow and glomerular filtration rate, the entire procedure is greatly simplified.

MEDICAL ILLUSTRATION

COLOR PHOTOGRAPHS SIMPLIFIED*

Valentine J. Connolly, Staten Island, N. Y.

It is generally conceded that color photography is a valuable asset in the presentation of post-mortem material. We have evolved a setup which, we believe, reduces the problems of equipment, expense, personnel, and time to a minimum.

The only equipment required is a miniature camera and a homemade frame of ordinary wood. The color film used is the least expensive made and it costs but ten cents for each picture. The photographic work can be done by a member of the regular staff, thus eliminating the need of specially trained individuals. This is essential since most hospitals do not have sufficient photographic work to employ a full-time photographer. Once the setup is calibrated, it takes less than one minute to take a picture.

The apparatus is shown in Fig. 1. For the most part it is made of wood. The base should be of heavy material to secure immobility and minimize vibration. The overall dimensions are about thirty inches by thirty inches. The area upon which the specimens are placed to be photographed (the millimeter rule in Fig. 1) is eighteen inches square. It is so fashioned that it can be slid up or down upon wedges made for that purpose. The wedges are placed in steps about one and one-half inches apart. The camera is attached by a wooden extension and placed so that the lens is centered exactly in the middle of the plate upon which the specimens are to be placed. The camera must be fixed rigidly and left in the proper position. Two No. 2 photofloods in reflectors (cardboard reflectors would do) are attached to upright posts at either side. The lights are set equidistant from the center of the specimen plate to illuminate evenly the area to be photographed. When satisfactorily arranged they should not be disturbed.

In our particular setup a Kodak Bantam with an Ektar F :2 lens of 45 mm. focal length is used. Almost any miniature camera could be adapted to the purpose. A portrait lens placed in front of the regular lens serves the dual purpose of decreasing the working distance and more fully utilizing the film area. According to the portrait lens used, the size of the image on the film may be increased one to two diameters. This is advantageous because it results in a larger screen image when projected. A polarizing screen may be added to the system to reduce reflection and high lights. Once it has been set to polarize the permanently placed light sources, care should be taken that it is not moved from that position.

---

*From the U. S. Marine Hospital.

Received for publication, Feb. 16, 1943.

To calibrate the setup the back of the camera is opened and a piece of ground glass placed at the film plane. The maximum and minimum distances of focus can be determined by placing a millimeter ruler on the specimen board and raising and lowering the board by steps while observing the image on the ground glass. The highest and lowest satisfactory steps are marked and when a small specimen is photographed the highest step is used; the lowest step is used for the large specimens. The board is then placed halfway between these points and with the lens wide open a critically sharp focus is obtained of the millimeter divisions on the ground glass. When this setting has been chosen it should not be moved by jarring. The shutter is then closed and color film inserted. The shutter speed should be set at the longest available time, one second if possible.

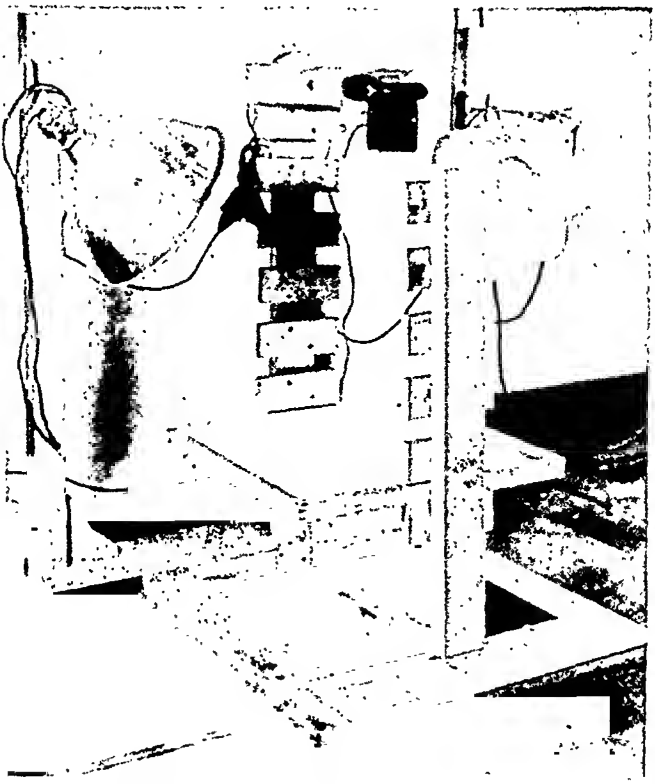

Fig. 1.—Photograph of apparatus showing fixed camera and lights and movable specimen board.

An average specimen, such as a heart, should be used for the calibration. The lens opening is closed to the lowest stop and an exposure made. The frame is moved along, the lens opening increased one stop, and another exposure taken. This procedure is repeated until all available lens openings have been used with the same shutter speed. The purpose of the slowest shutter speed is that the smallest lens opening will be utilized and consequently the greatest depth of focus will be obtained. After the films have been processed they may be projected to ascertain the best exposure. The lens stop is returned to this setting and kept there. The time setting remains stationary. To take subsequent pictures it is

merely necessary to place the specimen in the proper place and make the exposure. The only variable is the specimen.

The method is not without limitations. Exceptionally small and unusually large specimens cannot be reproduced well. Extremes in the color of some specimens, such as a dark blue lung or a white aortic vessel, will not be perfectly exposed at the medial exposure selected.

SUMMARY

A simplified method of taking color photographs of post-mortem specimens is presented. The necessity of taking light readings, focusing the specimen, and making the usual camera and light adjustments is eliminated. By reducing the variables to one (the specimen), excellent results are generally obtained.

BOOK NOTICES

Psychogenic Factors in Bronchial Asthma*

PSYCHOGENIC *Factors in Bronchial Asthma* consists of two volumes, the first a symposium by several members of The Institute for Psychoanalysis, Chicago, and the second a series of case reviews. Allergists, especially in the early days of this branch of medicine, were guilty of a one-sided outlook in their efforts to explain and cure all asthma entirely on the basis of skin tests. More recently their viewpoint has broadened so that good allergists today give as much attention to nonallergic factors such as focal infections and psychogenic problems, as they do to specific therapy. The reviewer's impression of the monograph under discussion is that the psychoanalyst, having discovered a psychogenic factor in some cases of asthma, has become guilty of the same hyperenthusiasm for his particular approach. The cases studied by the method of dream analysis are too few to be inclusively convincing. The observations are interesting and should be especially so to those allergists who may have devoted too little attention to psychogenic factors. One still wonders what happens to the asthmatic who doesn't dream.

Manual of Clinical Laboratory Methods†

A COMPREHENSIVE, technical, loose-leaf compendium of methods of interest to the technician.

Synopsis of Blood Diseases‡

THE purpose of this small book is to present in succinct form a synopsis of the salient features of diseases of the blood, addressed primarily to the senior student and the practitioner.

This is admittedly a difficult objective. The book is, hence, somewhat difficult to evaluate. It was once said that if the Tallqvist hemoglobin scale served no other purpose than to acquaint the observer with the appearance of drawn blood, a useful purpose was achieved. In like manner, if this book serves only to call attention to the complexities of diseases of the hematopoietic system, it may also serve to emphasize the difficulties embraced in their thorough understanding.

The Rat in Laboratory Investigation§

THIS book represents a compilation of some thirty different collaborators, all well-known workers in their respective fields. It covers everything about the rat, from love at first sight to psychoses and intestinal parasites in the oncoming generation. Every virtue, every weakness, and every peculiarity of the rat is fully and completely described. The anatomy,

Farris, Ph.D., Executive Director and Associate in Anatomy, Wistar Institute of Anatomy and Biology. Cloth, 488 pages, 178 illustrations, $7.50. J. B. Lippincott Company, Philadelphia, Pa.

physiology, biochemistry, pathology, psychology, and the full usefulness (or the lack thereof) of the rat in laboratory or experimental work is described in minute detail. Special chapters are devoted to breeding, diet, the teeth, digestion, metabolism, the central nervous system, psychologic phenomena, the circulatory system, biologic assay, hematology, osteology, radiology, histology, parasites and special diseases of the rat. Of particular interest are special sections on the eye of the albino rat, the surgery of the rat, and, of especial usefulness, a very extensive chapter (by Dr. Harold G. O. Holck) on dosage of drugs for rats. This latter chapter lists therapeutic and fatal dosages (when given in various ways) for some five hundred different drugs and is followed by a bibliography of 447 references. The chapter on "Technics for the Investigation of Psychological Phenomena in the Rat" (by Dr. George L. Kreezer) is followed by 678 references.

Well printed and admirably illustrated on excellent paper, this book is destined to become a sort of universal encyclopedia and reference work for all those who breed or use rats in experimental or investigational fields.

Macleod's Physiology in Modern Medicine*

SINCE the death of Dr. MacLeod his textbook on physiology has been edited by Philip Bard, Professor of Physiology at Johns Hopkins University School of Medicine with the collaboration of nine outstanding physiologists and pharmacologists. This is the ninth edition, the second under the new editorship. The usual number of additions and alterations have been incorporated, necessitated by advancing knowledge in the field. The work is so widely known that it does not require elaborate review. The paper used is especially desirable. Having a very faint green tinge, it is more restful on the eyes than the more usual white paper. The bibliography appears at the back of the book. It contains an innovation in that at the top of each page there is an index file referring to the pages in the book where the references appear.

Diseases of Metabolism†

DUNCAN'S *Diseases of Metabolism* is a contribution by fifteen outstanding contributors, well qualified in their fields, edited by Duncan, who has also contributed several sections. The subject matter adheres strictly to the title. The first half of the book deals with the metabolism and physiology of carbohydrates, fats, proteins, minerals, water, and vitamins. Expressed this way, one might have the impression that the discussion is a rehash of information long since available. Quite on the contrary, it consists of a splendidly arranged review of the abundant recent developments in the field. The first half of the volume alone places it in the category of better than average medical texts. It correlates much that has heretofore been available mostly in scattered articles.

Metabolic disturbances discussed in detail include undernutrition, obesity, xanthomatoses, gout, hyperinsulinism, diabetes insipidus, melituria and diabetes mellitus. The only chapter which might well have received more extensive discussion is that on undernutrition.

---

*Macleod's Physiology in Modern Medicine. Edited by Philip Bard, Professor of Physiology, Johns Hopkins University School of Medicine. With the Collaboration of Henry C. Bazett, Professor of Physiology, University of Pennsylvania, George R. Cowgill, Associate Professor of Physiological Chemistry, Yale University School of Medicine; Howard J. Curtis, Instructor in Physiology, Johns Hopkins University School of Medicine; Harry Eagle, Passed Assistant Surgeon, United States Public Health Service and Lecturer in Medicine, Johns Hopkins University School of Medicine; Chalmers L. Gemmill, Associate in Physiology, Johns Hopkins University School of Medicine; Magnus I. Gregersen, Professor of Physiology, College of Physicians and Surgeons, Columbia University; Roy G. Hoskins, Director of Research, Memorial Foundation for Neuro-endocrine Research; Research Associate in Physiology, Harvard Medical School; J. M. D. Olmsted, Professor of Physiology, University of California; Carl F. Schmidt, Professor of Pharmacology, University of Pennsylvania. Ninth Edition. Cloth, 1256 pages. The C. V. Mosby Company, St. Louis, 1941.

†Diseases of Metabolism. Detailed Methods of Diagnosis and Treatment. A Text for the Practitioner. Edited by Garfield G. Duncan, M.D., Chief of Medical Service "B," Pennsylvania Hospital; Associate Professor of Medicine, Jefferson Medical College, Philadelphia, Pennsylvania. Contributors: Walter Bauer, Abraham Cantarow, Garfield George Duncan, Ferdinand Fetter, Cyril Normal Hugh Long, Louis Harry Newburgh, Tom D. Spies, Hugh R. Butt, Tracy Donald Cuttle, Frank Alexander Evans, Friedrich Klemperer, Edward Halton Mason, John Punnett Peters, Leandro Maués Tocantns, Abraham White. Fully illustrated including 7 plates in color. Cloth, 985 pages. W. B. Saunders Company, Philadelphia and London, 1942.

The Avitaminoses*

NEW facts are evolving so rapidly in the study of vitamins that it was fortunate that Eddy and Dalldorf's *Avitaminoses* required a second edition after three years. Even so, the authors state that advances in our understanding of the vitamins necessitated a complete rewriting of most of the text. This volume will be of service to biochemists, clinicians and nutritionists alike. The first portion deals with the chemical nature of the vitamins. There follows a chapter on the functions of the vitamins in cellular oxidation which will enable the average reader to comprehend more clearly the action of these food components. The major portion of the volume is given to the description of the nature and function of each vitamin, the physiologic changes accompanying deficiency and the results of treatment. In an appendix, laboratory tests for vitamins are described and there is an excellent table of the vitamin content of most foods.

A Study of the Blood in Cancer†

IF ONE would read the last page of *The Blood in Cancer* first, one would be inclined not to read more. The observations are reminiscent of "Doctor" Abrams and Huckleberry Finn's reaction to the light of the moon.

Going backward in this volume, part III, describes many tests for cancer which have been recommended by various authors including urine tests, enzyme tests, and the like.

The major portion of the book deals with the author's studies of blood cytology in cancer. Dr. Gruner believes that unusually viscid blood without rouleaux but with tight cohesion of the red cells into islands with sharply defined contours and an early appearance of a dense fibrin network with granular matter in the meshes and actively moving leucocytes, reduction in the lymphocytes, irregular nuclear contours of the neutrophils, large polymorphous platelets, abnormality in the contour of the nucleus in the monocytes, and mitochondrial inclusions in the mononuclear leucocytes usually indicates malignancy.

*The Avitaminoses. The Chemical, Clinical and Pathological Aspects of the Vitamin Deficiency Diseases. By Walter H. Eddy, Ph.D., Professor of Physiological Chemistry, Teachers College, Columbia University; Director, Bureau of Foods and Sanitation, "Good House-[illegible]" and Gilbert Dalldorf, M.D., Pathologist to the Grasslands and Northern [illegible] Westchester County, N. Y. Second Edition. Cloth, 519 pages, $4.50. [illegible]ompany, Baltimore, 1941.

CLINICAL AND EXPERIMENTAL

BLOOD PRESSURE FLUCTUATIONS IN BRONCHIAL ASTHMA

I. CLINICAL OBSERVATIONS

HOWARD OSGOOD, M.D., BUFFALO, N. Y.

IN RECENT years there has been considerable discussion in medical literature on blood pressure in relation to bronchial asthma. This has been chiefly concerned with the question as to whether or not the mean systolic pressure shows a sustained rise or fall during an attack. It is not the purpose of the present paper to discuss this blood pressure change but rather to draw attention to certain fluctuations of the systolic pressure, which occur with each respiratory cycle during the asthmatic paroxysm, and to discuss their significance.

Minor fluctuations of the systolic blood pressure, synchronous with respiration, occur uniformly in normal individuals, the high point coming during expiration, the low point during inspiration in quiet breathing.

The respiratory fluctuations which occur in patients suffering from an attack of bronchial asthma are of greater amplitude. When the asthmatic paroxysm is severe, these fluctuations may be of sufficient magnitude to produce a noticeable waxing and waning of the radial pulse to palpation. A more common finding, however, is a lesser degree of fluctuation, not appreciable at the wrist, but only noted when the blood pressure is taken by a sphygmomanometer. The failure of these fluctuations to be detected ordinarily in the radial pulse may explain why they are seldom mentioned in medical texts dealing with allergic conditions or in general medical texts in connection with bronchial asthma. Physicians whose practice entails the observation of many asthmatic patients have undoubtedly noted them repeatedly.

From the Medical Services and Allergy Clinic of the Buffalo General Hospital, Buffalo, N. Y.

Received for publication, Sept. 8, 1942.

Sihle,[1] in 1903, stated that a majority of asthmatic patients during a paroxysm show a variable lowering of blood pressure, "so that in the same patient, in the course of five minutes, not infrequently values of 90, 70, 100, 85, 75 can be observed." He did not note that these were related to the respiratory cycle.

Tinel and Jacquelin[2] studied a number of asthmatic patients by means of a cuff over the humeral artery and kymograph tracings of the pulse. They noted the changes produced in the tracings by varying the pressure in the cuff. They found (1) that during the attack of asthma, coincident with inspiration, there was a considerable diminution of the amplitude of the pulse tracings, which was absolutely constant during the course of each paroxysm, and which ceased with its termination; (2) that there was a fall of the "maximum arterial tension" at the onset of dyspnea, amounting to 20 mm. or 30 mm. Hg, with a return to the former level with the end of the paroxysm; and (3) that an *elevation* of the "minimum arterial tension" occurred at the onset of the paroxysm, resulting in a diminution of the oscillometric amplitude of the pulse. They concluded that these changes were due to some interference of the blood flow into the right heart and through the pulmonary circulation.

Rist, who discussed Tinel and Jacquelin's[2] paper, used the same method to determine the fluctuations of blood pressure which I have employed. He found that the systolic pressure (in various conditions) may vary as much as 30 *mm. Hg* between inspiration and expiration and maintained that the inspiratory suppression of the pulse noted by Tinel and Jacquelin was due to a lowering of the systolic pressure, and "was only an exaggeration of a normal phenomenon."

Rackemann[3] states that the respiratory fluctuations of the systolic blood pressure in asthma may be wide and are roughly parallel with the severity of the asthma. He also notes that there may be well-marked fluctuations in the presence of emphysema and many wheezes, when the severity of the asthma is not marked.

Feinberg[4] observes that during the asthmatic paroxysm, as a rule, the blood pressure rises and varies markedly with inspiration and expiration.

Detailed studies of the respiratory blood pressure fluctuations in bronchial asthma have not, so far as I am aware, appeared in the literature, and for this reason I present my findings.

METHOD

With practice, fluctuations of the systolic blood pressure in human beings, synchronous with the respiratory cycle, may be readily observed and measured by the auscultatory method, the stethoscope being placed over the antecubital space.

The usual 13 cm. cuff is applied to the upper arm and the sphygmomanometer placed close to the patient, so that it may be read and at the same time the patient's respirations can be seen "out of the *corner* of the eye." The cuff is inflated to a pressure above the highest systolic reading. The pressure is then slowly lowered, not more than 2 or 3 mm. per breath, the respiratory movements of the chest or abdomen being closely noted meanwhile. A point in the pressure will presently be reached, where a few beats will be heard at the elbow

at a certain moment in expiration. If the cuff pressure is held at this point, the auscultatory beats will disappear during the remainder of expiration and during the succeeding inspiration. There will be a trough of silence lasting until the corresponding moment in the next expiration, when the beats will reappear. The reading of the manometer at this point will indicate the highest level reached by the systolic pressure during the respiratory cycle.

As the cuff pressure is then further lowered slowly, more and more beats will be heard, first throughout expiration and then during inspiration. The manometer reading at the moment when beats are just heard throughout both inspiration and expiration marks the lowest point to which the systolic pressure falls during respiration. The difference between these two readings denotes in mm. Hg the amplitude of the respiratory fluctuations of the systolic pressure. The diastolic reading is taken in the usual way.

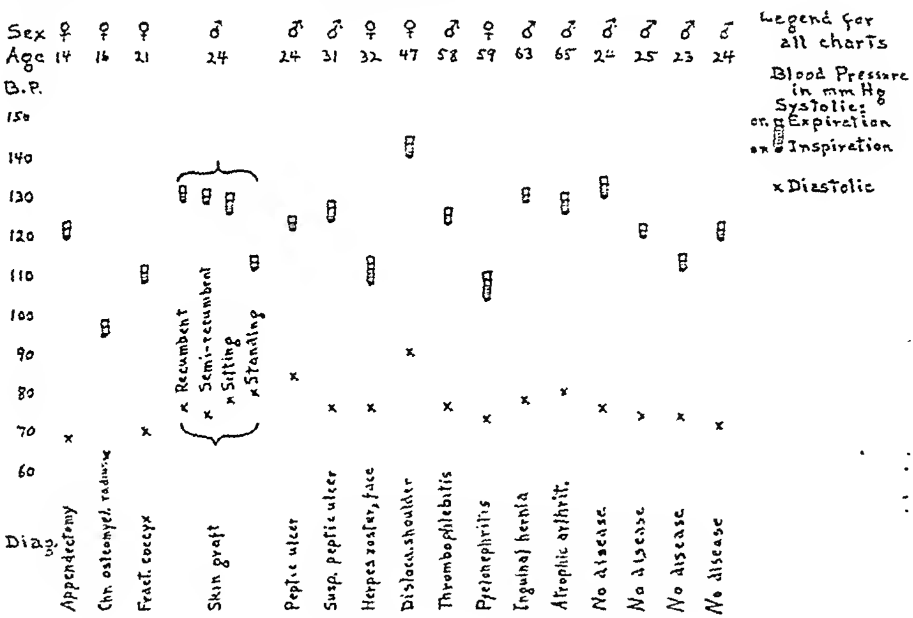

Fig. 1.—Normal respiratory fluctuations of the systolic blood pressure.

In my observations on asthmatic patients, and on normal individuals at rest, the high point of the systolic fluctuation has occurred uniformly during expiration and the low point during inspiration. It is possible that there may be circumstances where there is a reversal in phase of the high and low points, but I have not met with it. The diastolic pressure varies very slightly with respiration in asthma, but I have not included this variation in my studies. It is worth further attention.

In order to determine the normal limits of the respiratory fluctuation with this technique, determinations have been made on a number of subjects, both on healthy persons and on nonasthmatic hospital patients who were not acutely ill and were not suffering from cardiac, pulmonary, renal, or intrathoracic disease.

Fig. 1 shows the readings on sixteen such persons. The maximum fluctuation of the systolic pressure during respiration is 6 mm. Hg: the minimum is

2 mm. The average for the ten males is 3 mm.; for the six females it is 4 mm. Random observations on other similar individuals have shown an occasional fluctuation up to 12 mm. Hg in the absence of known disease.

OBSERVATIONS ON ASTHMATIC PATIENTS

Over the past three years determinations of the respiratory systolic fluctuation have been made on many asthmatic patients. The findings on some of these patients are here presented, with the high and low points of the systolic fluctuation indicated on the charts. The estimated severity of the asthmatic dyspnea at each reading is shown by the black columns at the bottom of the figures, with the dates beneath.

Fig. 2 shows findings on two patients on different days, the first reading in each being taken during an asthmatic paroxysm, the subsequent readings made when the paroxysm had subsided. In both, the fluctuation was wide when dyspnea was pronounced, diminishing when the dyspnea decreased.

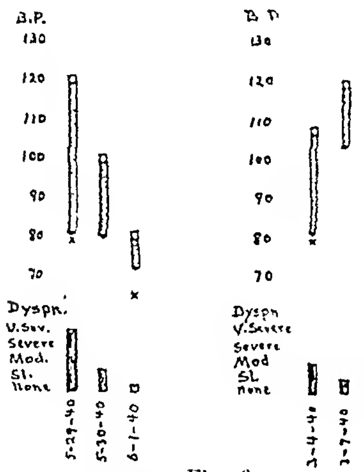

Fig. 2.

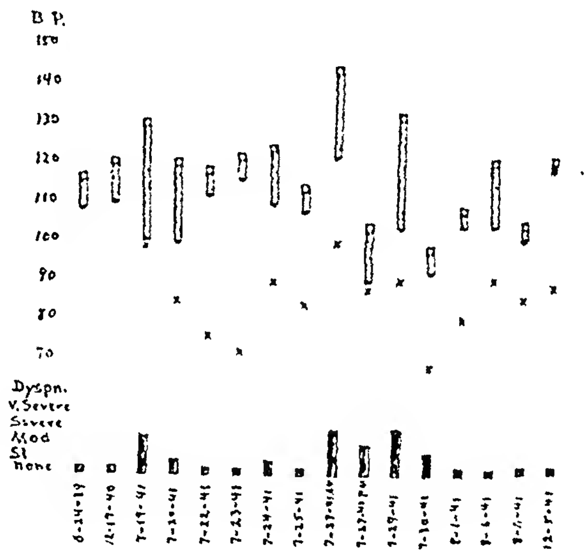

Fig. 3.

Fig. 2.—Respiratory systolic fluctuations at height of asthmatic paroxysm and after its subsidence. Patient B. B., female, 36 years of age, sensitive to inhalants and foods, and patient F. G., female, 38 years of age, sensitive to inhalants.

Fig. 3.—Respiratory systolic fluctuations in a chronic asthmatic patient, L. B., female, 48 years of age, with extrinsic and intrinsic factors as causative agents.

Fig. 3 presents readings taken at intervals over a period of two and one-half years on a chronic asthmatic patient whose asthma was due to intrinsic as well as inhalant factors. It will be noted that the respiratory systolic fluctuation followed closely the severity of the asthma, although on a few occasions it did not decrease to normal limits even though the patient was not apparently in distress. This corresponds to Rackemann's observation. One reading (third from the left) shows a fluctuation of 30 mm., the systolic pressure falling during inspiration almost to the diastolic level. This phenomenon has been noted in other patients when the asthma has been very severe.

Fig. 4 shows blood pressure readings taken over a period of a month (July 7 to August 7) on a patient 52 years of age who was very sensitive to grass and

weed pollens and to certain inhalants. During this month she passed through a very severe attack of asthma, being in an oxygen tent for five days. The respiratory systolic fluctuations parallel the severity of her asthma. Between July 20 and 29 there was a remission, at which time the fluctuations decreased to normal or near normal limits. A short recrudescence of the asthma then occurred with a corresponding increase in the systolic fluctuations, at one reading amounting to 30 mm. On August 7 she was asthma-free, and the fluctuation was 4 mm. Two readings in November, during a shorter attack of asthma, again disclosed an increase in the fluctuation. In this patient the mean systolic level tended to rise during a spell of asthma.

The determination of the respiratory systolic fluctuation has been useful in estimating the degree of bronchial obstruction present in a given patient at a given moment, as demonstrated in the following observations:

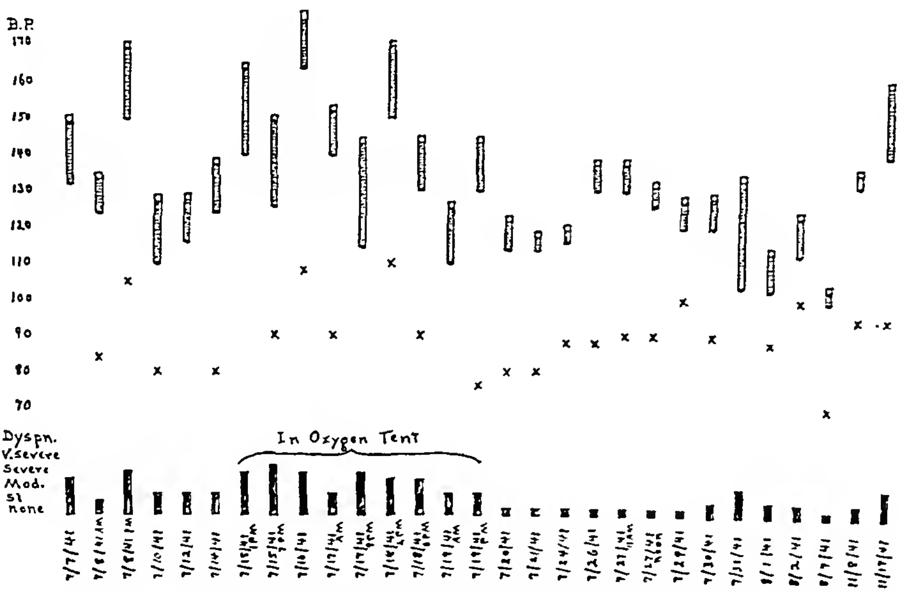

Fig. 4.—Respiratory systolic fluctuations throughout a prolonged attack of asthma. Patient G. H., female, 58 years of age, sensitive to pollens and inhalants.

An unmarried woman (Fig. 5), 53 years of age, was sensitive to orris, house dust, and grass pollen. She had had a number of moderately severe attacks of asthma and was highly apprehensive of its recurrence. A blood pressure reading during an asthma-free period yielded a respiratory systolic fluctuation of 5 mm. Three days later she complained of respiratory distress and a paroxysmal cough. When seen she was greatly excited and apprehensive, but to close observation she did not appear to be having much respiratory difficulty; an examination of her lungs showed only a few signs of bronchial spasm. The respiratory systolic fluctuation was 10 mm. With assurance and while preparations were being made to administer epinephrine in oil (but before it had been injected), her cough and distress subsided greatly. Ten minutes after the injection the respiratory systolic fluctuation was 7 mm. Here the distress was largely mental, and the blood pressure readings bore out the clinical impression that

there was little bronchial obstruction present. A stiff dose of sedative might have given as much relief as epinephrine, perhaps even more.

That relief of the bronchial asthma during an attack will bring about a reduction of the respiratory systolic fluctuation to within normal limits is demonstrated in Fig. 6. The patient was a married woman, 41 years of age who was primarily sensitive to orris root, with lesser sensitivity to house dust and flour mill dust. She had recurring attacks of severe asthma, but had developed no complicating conditions. Two blood pressure readings on December 2 and 4, when she was asthma-free, had shown respiratory systolic fluctuations of 3 and 4 mm., respectively. She was seen at 4 P.M. on January 13 in the midst of a

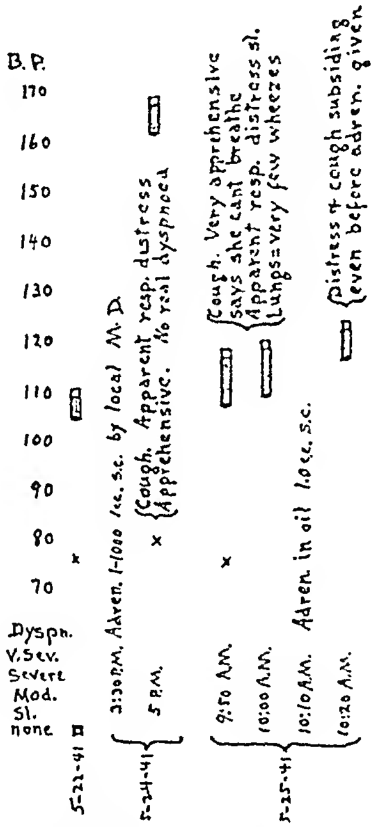

Fig. 5.—Respiratory systolic fluctuations in apparent asthmatic dyspnea but with little bronchial obstruction. Patient E. B., female, 53 years of age, sensitive to orris, dust and grass pollen.

severe attack; her lungs were full of wheezes. The respiratory systolic fluctuation was 30 mm. Injections of 0.25 c.c. epinephrine, 1 to 1,000, and 1 c.c. epinephrine in oil, 1 to 500, were given at 4:10 P.M. Some relief was noted at 4:20 P.M. and by 4:35 P.M. she was free of dyspnea, and the wheezes had disappeared from her lungs. Readings of the respiratory systolic fluctuation showed a progressive decrease in amplitude, until at 4:35 P.M. the fluctuation was 6 mm. A subsequent reading three months later, when she had no asthma, showed a fluctuation of 3 mm.

When adequate relief is not secured after palliative treatment, the continued dyspnea is reflected in a persistent wide respiratory systolic fluctuation.

In Fig. 7 are presented the findings in such an instance. The patient was a trained nurse, 43 years of age. She suffered from asthma at intervals throughout the year, with marked exacerbations during the grass season. Skin tests were negative except for a delayed positive to ragweed. She was seen on June 30 while in a severe asthmatic attack. The respiratory systolic fluctuation on two readings, taken ten minutes apart, were 26 and 45 mm., respectively. Injection of 0.6 c.c. epinephrine, 1 to 1,000, and 1 c.c. epinephrine in oil, 1 to 500, were then given. Five minutes after the injection she reported slight relief, and her respiratory systolic fluctuation had decreased to 16 mm. However, ten minutes later the relief had not been maintained and the fluctuation was 30 mm.

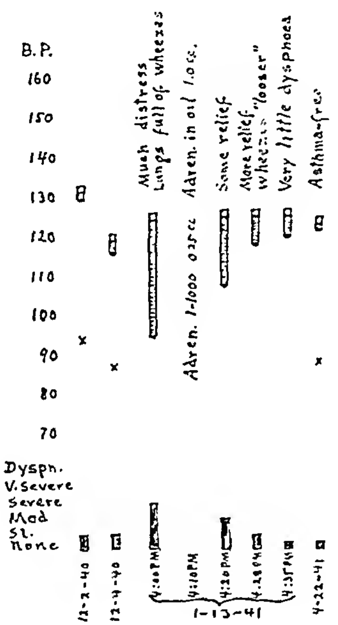

Fig. 6.

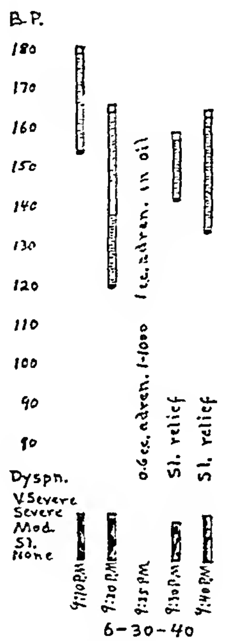

Fig. 7.

Fig. 6.—Respiratory systolic fluctuations before and after relief of an asthmatic paroxysm. Patient T. W., female, 41 years of age, sensitive to orris and other inhalants.

Fig. 7.—Respiratory systolic fluctuations when relief is not afforded by treatment. Patient M. M., female, 43 years of age, sensitive to pollens and inhalants.

DISCUSSION

The increased respiratory fluctuations of the systolic blood pressure reported above have been a constant finding in bronchial asthma.

A similar fluctuation (sharp fall in the systolic blood pressure) can be produced momentarily by attempting a deep inspiration with the nose and glottis closed (Mueller's experiment cited by Tinel and Jacquelin[2]). Certain experiments on cats, reported by me,[5] have shown fluctuations of the carotid blood pressure, similar to those in asthma, when obstruction to respiration was introduced at the trachea. Other experiments with increasing respiratory obstruction at the mouth in healthy young men, induced by progressively constricting a rubber mouthpiece, reported by me in the same paper,[5] also demonstrated an increasing fluctuation of the systolic blood pressure. In both cats and men, the amplitude of the fluctuations paralleled the degree of obstruction; and the

timing of the high and low points of the fluctuation in the respiratory cycle was the same as I have found it in asthmatic patients.

The mechanism by which this fluctuation is produced is probably complex. Reid,[6] in a recent article, has made some very interesting remarks on respiration as a factor in maintaining the circulation, which may throw light on the subject. The gist of his remarks is that during inspiration the intrathoracic pressure is lowered, favoring an inflow of blood from the large systemic veins into the chest, while at the same time the descent of the diaphragm raises the intra-abdominal pressure and so propels the blood through the vena cava into the large thoracic veins and to the right side of the heart. Also with the expansion of the lungs, the smaller pulmonary vessels dilate, so that a definite proportion of the whole blood volume is temporarily pooled in the vascular bed of the lungs. With the succeeding expiration, this pooled blood, plus the normal flow, is actively expelled from the lungs toward the left side of the heart by the elastic contraction of the lung tissue toward the hilum.

In bronchial asthma the intrathoracic and intra-abdominal pressure changes would be exaggerated. On *inspiration* it is possible that under the greater negative intrathoracic pressure[7] the vascular bed of the lungs dilates more than normal, pooling a greater amount of blood and withholding it from the left side of the heart. This would reduce the left ventricular output and so lower the systemic systolic pressure.

On *expiration*, which is considerably prolonged in bronchial asthma, there is an increased rise in the intrapleural pressure to even slightly above the atmospheric level.[7] This along with the elastic recoil of the lungs would induce an expulsion of the larger pool of blood in the lung-bed toward the left side of the heart, and a considerable increase of the left ventricular output would result, with a consequent rise in the systemic systolic blood pressure. Enhancing this greater supply of blood to the left side of the heart a moment later, but still during expiration, would be a greater supply of blood to the right side of the heart, as the increased intra-abdominal pressure, incident to the intense expiratory effort, propels more blood upward through the great veins into the chest. Since the intrathoracic pressure does not rise far above atmospheric pressure, whereas the intra-abdominal pressure starts at atmospheric level and is then increased by the vigorous action of the abdominal muscles in forced expiration, it is probable that this heightened pressure transmitted to the column of blood filling the vena cava would counteract any tendency of the positive pressure in the chest to collapse the veins entering the right side of the heart.

Whatever the true explanation, it is evident that the marked drop and subsequent rise of the systemic systolic blood pressure during the respiratory cycle in bronchial asthma is dependent upon some disturbance of the normal flow of blood through the lungs to the left auricle. This disturbance in turn is caused by the excessive fluctuations of the intrathoracic pressure induced by the obstruction to respiration in the smaller bronchi and bronchioles.

The parallelism between the presence and amplitude of the respiratory systolic blood pressure fluctuation on the one hand, and the severity of the asthma on the other, has been close, though not to a mathematical degree. I be-

lieve it may therefore be taken as an indirect and approximate measure of the degree of bronchial spasm or obstruction present and so may be a useful clinical sign. Conversely observations on the behavior of these fluctuations under various circumstances in bronchial asthma may offer a new method for studying the mechanism of the bronchial obstruction in this condition.

A paper is now in preparation covering observations on the effects of the administration of epinephrine and theophyllin ethylenediamine (aminophyllin) on these blood pressure fluctuations in asthmatic patients.

CONCLUSIONS

1. Wide fluctuations of the systolic blood pressure, synchronous with respiration, are a constant finding in bronchial asthma. The high point of the fluctuation occurs during expiration, the low point during inspiration.

2. The amplitude of these fluctuations parallels closely the severity of the asthma.

3. When the asthma has subsided, the fluctuations return to normal.

4. This respiratory systolic fluctuation is a useful clinical sign, indicating approximately the degree of respiratory obstruction present.

5. Observations on these fluctuations may be of value in studying the mechanism of bronchial asthma.

I wish to express my appreciation to Dr. Francis E. Ehret for his labor in going over innumerable records of asthmatic patients and abstracting the data on which this paper is based.

U-WAVE PATTERNS IN THE ABNORMAL ELECTROCARDIOGRAM*

SYLVAN D. SOLARZ,† M.D., AND STEPHEN R. ELEK,‡ M.D., CHICAGO, ILL.

THERE has been a dearth of literature on the U wave of the electrocardiogram and little is known concerning its cause and significance. The literature has recently been reviewed by Papp[1] who defined the dimensions of this wave and stressed the frequency of inverted U waves in clinical heart disease. Nahum and Hoff[2] presented evidence from which they concluded that the U wave is related to the supernormal phase of the myocardium and that it marks the period when premature ventricular systoles occur most frequently. Recent studies, including those from this laboratory,[3, 4] showing that many abnormal electrocardiograms fall into definite patterns, suggested the desirability of determining the U-wave contours occurring in these various patterns.

The electrocardiograms were selected at random from the files of the heart station according to the electrocardiographic patterns. Most of the records had chest leads CF_2 and CF_4 as well as the limb leads. A few had only one chest lead (CF_2) and a few had no chest leads. Serial tracings, especially in the cases of myocardial infarcts, were available in many instances.

Three chief electrocardiographic patterns were analyzed: (a) ventricular preponderance (425 cases), diagnosed according to criteria established in this department;[3-5] (b) myocardial infarction (350 cases); and (c) intraventricular block (QRS duration over 0.12 sec.) (210 cases). A small series of cases of pericarditis (6 cases), of acute glomerulonephritis (3 cases) and of pulmonary embolism (6 cases) were also studied.

CRITERIA FOR THE NORMAL U WAVE

Optimal heart rates for the identification of the U wave are listed by Papp[1] as 60 to 110 beats per minute. Below this rate, the U wave tends to fuse with the T; above this rate it tends to be incorporated with the P wave. In the course of this study a number of records were found in which normal or abnormally tall, upright U waves followed so closely after the T wave as to simulate notched, diphasic, or bizarre T waves (Fig. 1-*A*, *B*). These can be distinguished by measuring the QRST interval of the other leads. In cases of tachycardia examples of amalgamation of U and P waves occurred (Figs. 2, 5-*A*). Here the distinction can be made by measuring the P-R interval of the other leads. Furthermore, in records of auricular fibrillation, with slow or moder-

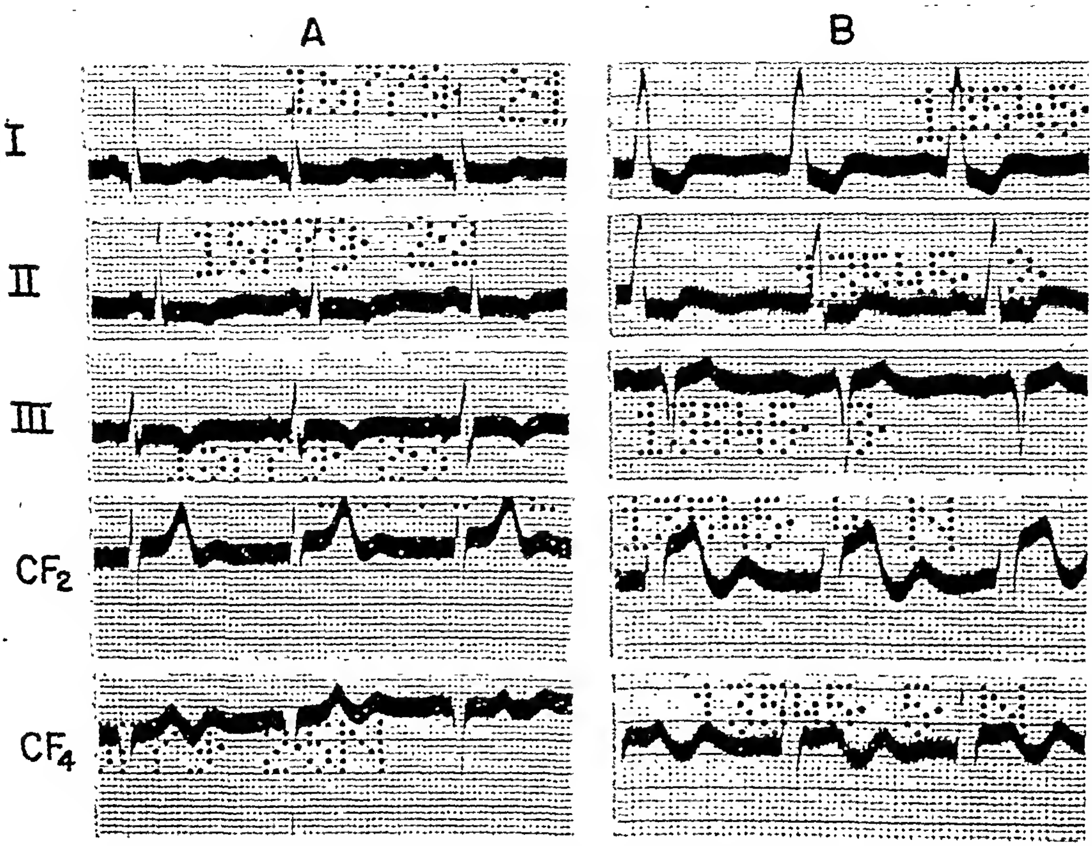

Fig. 1.—Simulated bizarre T waves caused by large U waves following closely after the T waves. *A.* In Leads I, II, CF2 and CF4 normal, upright U waves are seen giving the false impression of polyphasic T waves. *B,* Abnormally tall, upright U waves in the chest leads result in a configuration superficially resembling bizarre T waves.

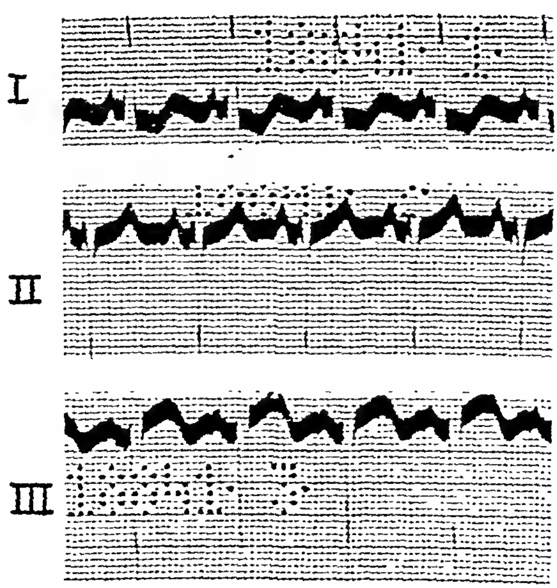

Fig. [illegible] the T and P waves in Lead III. This resembles a notched P wave. [illegible] in all three leads are within normal limits and the P wave in Lead [illegible] omparing the P-R intervals in the several leads.

ately fast ventricular rates, large upright U waves may exist, especially in the chest leads, lending the illusion of P waves (Fig. 3). These observations indicate that the recognition of even the normal U wave is important in avoiding errors in description of the P and T waves and in measurement of the P-R interval. The error in diagnosis of mistaking a U for a P wave in cases of auricular fibrillation is, of course, evident. In addition, the presence of the U wave means that the isoelectric level can best be determined in the interval between U and P.

The criteria of Papp[1] for normality of the U wave were accepted in our study. The normal U wave is upright, varying in height from 0.25 to 2.0 mm.

I

II

III

CF_2

CF_4

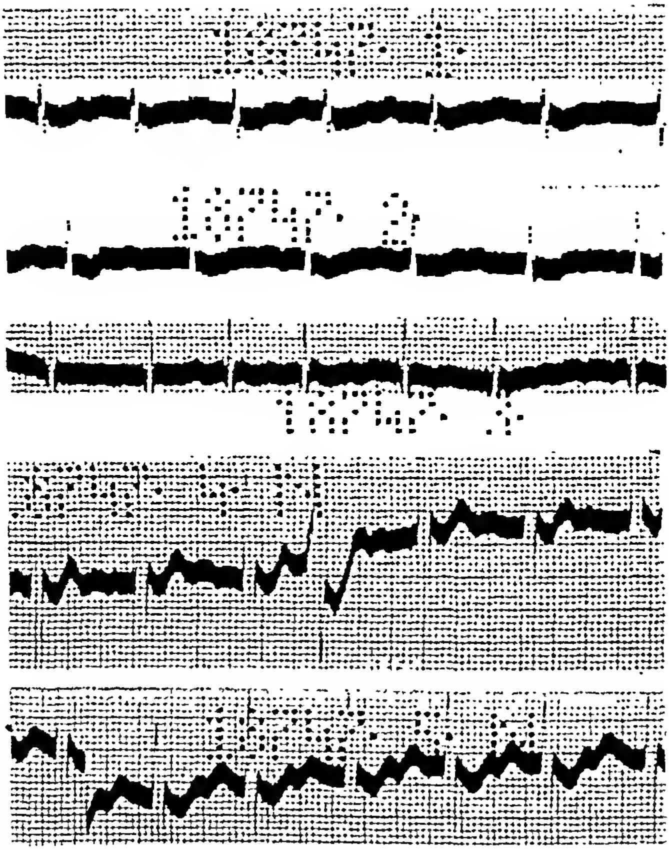

Fig. 3.—Auricular fibrillation of the coarse type. The U waves in leads CF_2 and CF_4 superficially give the impression of large P waves and might lead to an erroneous diagnosis.

I

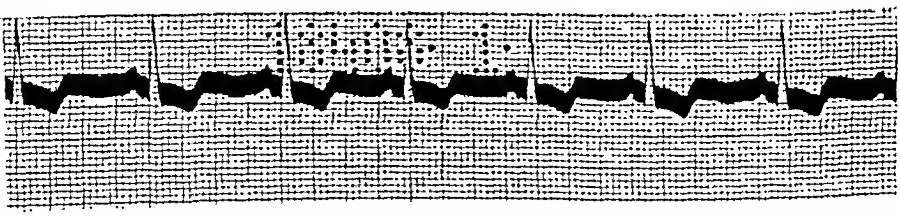

Fig. 4.—The downward bowed T-P segment in Lead I which is equivalent to an inverted U wave. Discussed in text.

and in duration from 0.18 to 0.24 sec. The U wave was considered abnormal when inverted, diphasic, or upright and taller than 2 mm. Another abnormality found by us especially in Lead I was the occurrence of a negative bowing of 1 mm. or more in the T-P segment of the electrocardiogram. In several records with this phenomenon the presence of a marked sinus arrhythmia soon made it evident that this bowing was due to the existence of an inverted U wave, for in the long T-P intervals the negative U wave was apparent; in the short T-P intervals only the downward bowing remained, the end of the U wave being invisible (Fig. 4). Hence this downward bowing of the T-P segment is regarded as an inverted U wave. A similar but normal upward bowing of the T-P segment may also be found.

THE U-WAVE PATTERNS IN HEART STRAIN

An analysis of 75 consecutive cases of right ventricular preponderance showed no abnormal U waves. Hence, the analysis of this pattern was not pursued further.

Examination of 350 cases of various types of left ventricular preponderance revealed 38 cases with abnormal U waves. Three cases were of the first type, 23 of the second type, 11 of the mixed type, and one of the concordant type.[4, 5]

The U-wave abnormality in the 3 cases of the first type of left ventricular preponderance consisted of U-wave inversion in CF_4 and on 2 occasions in Lead I. One instance of the inverted and one of the diphasic U were encountered in CF_2.

TABLE I

U-WAVE CONFIGURATION IN LEFT VENTRICULAR PREPONDERANCE OF THE SECOND TYPE IN THE 23 CASES SHOWING U-WAVE ABNORMALITIES

LEAD	U INVERTED	U UPRIGHT AND NORMAL	U UPRIGHT AND ABNORMAL	U DIPHASIC 1ST PHASE UP	U DIPHASIC 1ST PHASE DOWN	U ISO-ELECTRIC
I	17	1	0	0	0	5
II	2	5	0	0	0	16
III	0	11	0	0	0	12
CF_2	3	13	1	2	0	4
CF_4	11	7	1	0	1	2*

*One record had no CF_4.

Table I summarizes the configuration of the U wave in the second type of left ventricular preponderance. U-wave inversion was most frequent in Lead I, occurred rarely in Lead II and was not encountered in Lead III. It occurred more frequently in CF_4 than in CF_2. In addition, in the chest leads abnormal upright and diphasic U waves were found. It would appear, therefore, that the idealized pattern of the U wave in this type of left ventricular preponderance consists of an inverted U_1, an upright or isoelectric U_2 and U_3, an upright U in CF_2 and an inverted U in CF_4 (Fig. 5-*A*). The lead distribution of the abnormal U waves in this pattern is shown in Table VII. It is evident from this table that U-wave abnormalities occurred most frequently in Lead I and next in frequency in Lead CF_4.

A similar trend is revealed in the mixed type of left ventricular preponderance (Tables II and VII). In the case of the concordant type of left heart strain the U was found to be inverted in Lead I.

THE U-WAVE PATTERNS IN INTRAVENTRICULAR BLOCK

An analysis of 75 consecutive cases of intraventricular block of the S type[5] revealed no abnormal U waves. Hence, no further analysis was carried out in this group.

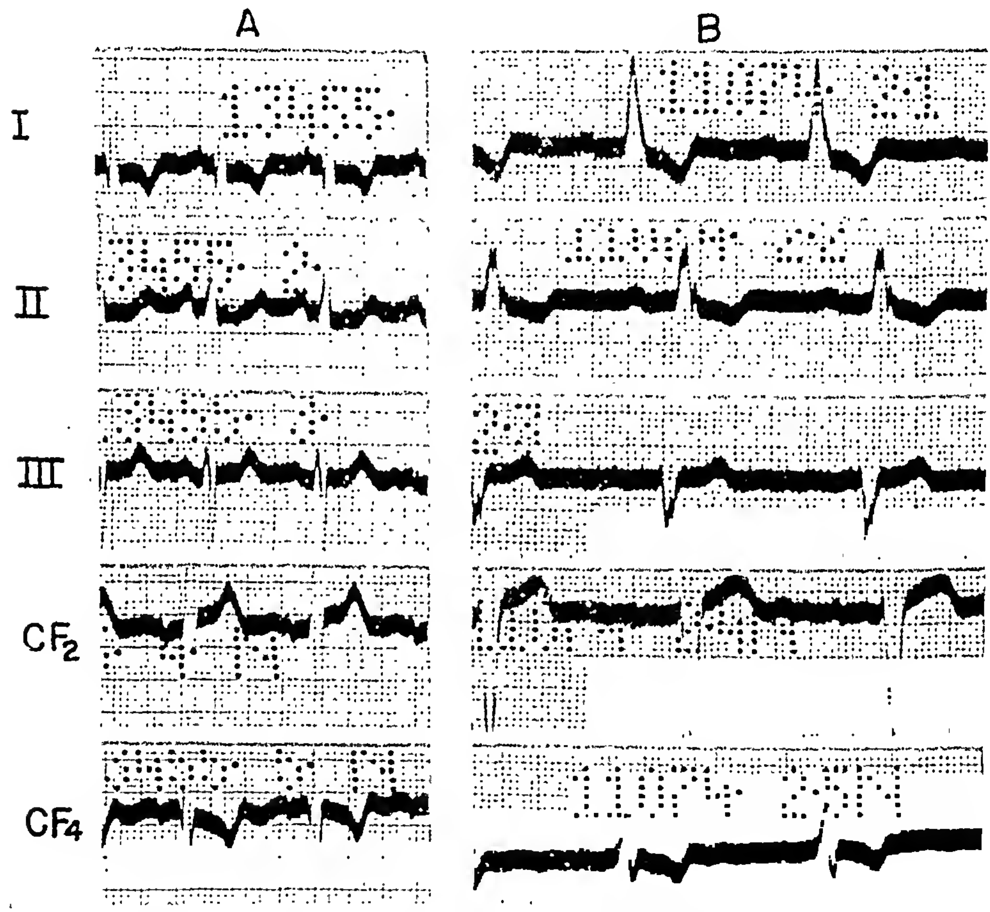

Fig. 5.—*A*. Second type of left ventricular preponderance. The U wave is inverted in Leads I and CF_4 and the T waves in these leads are also inverted. Note the U wave in Lead III is closely followed by the P wave and gives the false impression of a bizarre P wave (cf. Fig. 2). *B*. Intraventricular block of the common type. The U wave is inverted in Leads I and CF_4, and the T waves in these leads are inverted also.

Of the 135 cases of the common type of intraventricular block analyzed 17 had abnormal U waves; these findings are summarized in Table III. U-wave abnormalities occur most frequently in Leads I and CF_4 (Table VII). Thus a synthetic pattern in this type of intraventricular block would consist of inverted U waves in Leads I and CF_4 with normal upright or isoelectric U waves in Leads II and III and normal upright U waves in CF_2 (Fig. 5-*B*); this pattern is similar to that found in the second type of left ventricular preponderance.

*One record had no CF_4.

THE U-WAVE PATTERNS IN MYOCARDIAL INFARCTION PATTERNS

Three hundred fifty cases with myocardial infarction patterns were analyzed, and in 39 abnormal U waves were seen. The latter included 18 of the anterior wall pattern, 11 of the posterior wall pattern, and 10 of the atypical patterns. Tables IV, V, and VI summarize the U-wave findings in these 39 cases.

In the anterior wall infarction series U-wave inversion was seen most frequently in CF_4 and next in frequency in CF_2 (Table VII). Thus, the idealized pattern of the U wave in anterior wall infarction consists of inversion of U in the chest leads, isoelectric or inverted U in Lead I, isoelectric U in Lead II, and isoelectric or upright U in Lead III (Fig. 6-*A*). Furthermore, analysis of 17 cases having serial curves showed that the U-wave abnormalities occurred only during the T stage and not the S-T stage.

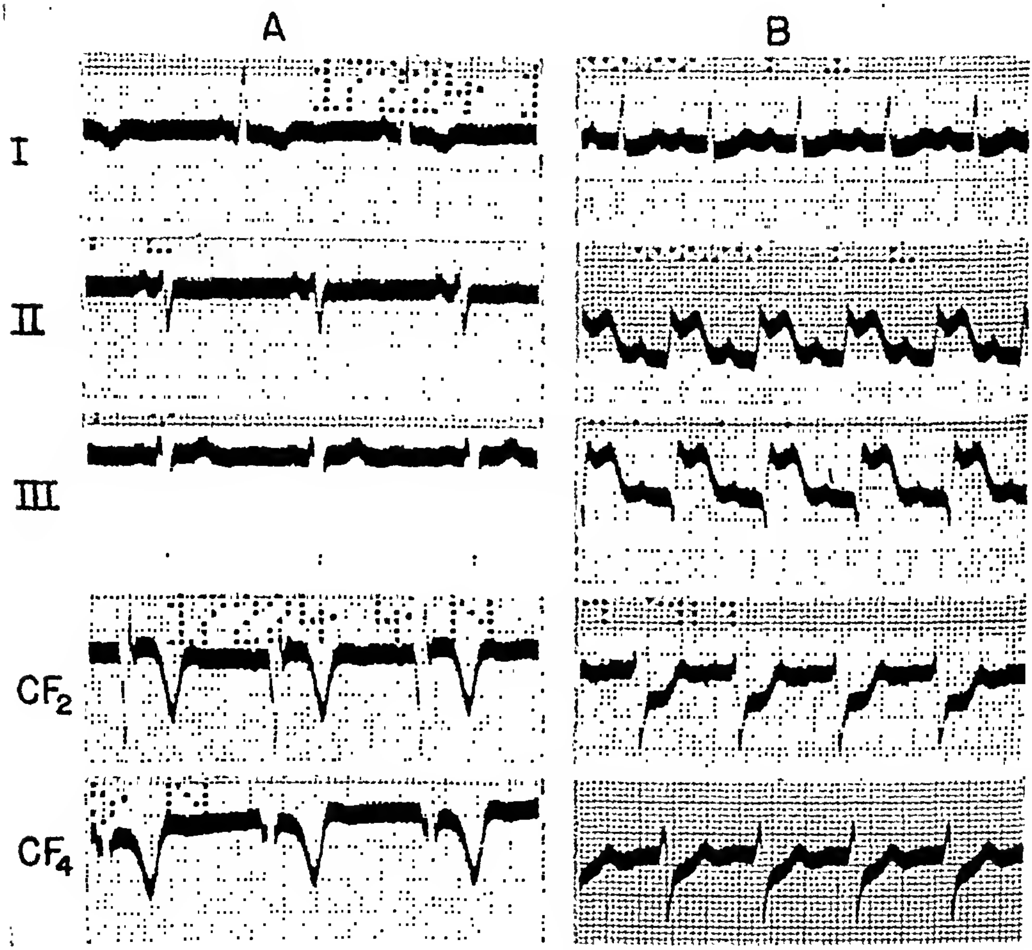

Fig. 6.—*A*. Anterior wall infarction in the healing (T) stage. The U wave in Leads I, CF_2 and CF_4 is inverted, and the U and T waves are concordant in direction in all leads. *B*. Very recent posterior wall infarction in the S-T stage (monophasic curve). The U waves in Leads CF_2 and CF_4 are inverted, and the S-T segments are markedly depressed. There is discordancy in direction between the U wave and T in these leads.

In the posterior wall infarction pattern Lead CF_4 again showed the greatest frequency of abnormal U waves (consisting of inversion) although scattered instances of abnormal U waves in the other leads were seen (Tables V and VII) (Fig. 6-*B*). Unlike the anterior wall infarcts, the U-wave abnormalities in posterior wall infarction were seen more commonly in the S-T stage.

TABLE VI

U-WAVE CONFIGURATION IN ATYPICAL MYOCARDIAL INFARCTION PATTERNS IN THE 10 CASES WITH U-WAVE ABNORMALITIES

LEAD	U INVERTED	U UPRIGHT AND NORMAL	U UPRIGHT AND ABNORMAL	U DIPHASIC		U ISO-ELECTRIC
				1ST PHASE UP	1ST PHASE DOWN	
I	2	1	0	1	0	6

CF_4	8	0	0	2	0	0

TABLE VII

LEAD DISTRIBUTION OF ABNORMAL U WAVES IN THOSE INDIVIDUAL CASES SHOWING U-WAVE ABNORMALITIES

DIAGNOSIS	LEAD I	LEAD CF_4	LEADS I AND CF_4	LEAD CF_2	LEADS CF_2 AND CF_4	LEADS I, CF_2 AND CF_4	OTHER LEAD COMBINATIONS
Left Ventricular Preponderance, Mixed Type	4	0	2	0	3	1	1
Left Ventricular Preponderance, 2nd Type	9	4	4	0	2	1	3
Left Ventricular Preponderance, 1st Type	1	0	0	1	0	1	0
Left Ventricular Preponderance, Concordant Type	1	0	0	0	0	0	0
Intraventricular Block, Common Type	8	2	2	1	1	1	2
Anterior Wall Infarction Pattern	0	6	0	1	6	4	1
Posterior Wall Infarction Pattern	0	4	1	1	2	1	2
Atypical Infarction Patterns	0	4	1	0	4	0	1

Unlike the anterior and posterior wall patterns, the U-wave abnormalities in atypical infarction patterns occurred at all stages of the electrocardiographic evolution.

THE U-WAVE PATTERNS IN OTHER CONDITIONS

No abnormal U waves were found in the series of records of diffuse pericarditis, acute glomerulonephritis, or pulmonary embolism examined.

CORRELATION OF THE DIRECTION OF THE ABNORMAL U WAVES WITH THE DIRECTION OF THE T WAVE AND THE DEVIATION OF THE S-T SEGMENT

An impression was gathered in the course of this study that inverted U waves were usually associated with inverted T waves. In fact, Ashman and Hull[6] state that inverted U waves are commonly associated with inverted T waves. This was checked in all the records with regard to the concordancy of deviation of the U and T waves.

In left ventricular preponderance (all types) there was generally a concordancy in direction of the abnormal U waves and in the direction of T. This was most prominent in Leads I and CF_4 (Table VIII). This correlation was even more striking in the common type of intraventricular block since no instance of discordancy in direction of T and U occurred.

TABLE VIII

CORRELATION OF THE DIRECTION OF THE ABNORMAL U WAVE WITH THE DIRECTION OF THE T WAVE IN LEFT VENTRICULAR PREPONDERANCE AND IN THE COMMON TYPE OF INTRAVENTRICULAR BLOCK IN THE CASES WITH ABNORMAL U WAVES*

*A diphasic U wave was considered equivalent to an inverted one.
†2 U waves were inverted; one, upright and abnormal.

TABLE IX

CORRELATION OF DIRECTION OF ABNORMAL U WAVE WITH DIRECTION OF S-T DEVIATION AND WITH DIRECTION OF T WAVE IN CASES SHOWING ABNORMAL U WAVES*

DIAGNOSIS	S-T SEGMENT						T WAVE					
	LEAD I		LEAD CF_2		LEAD CF_4		LEAD I		LEAD CF_2		LEAD CF_4	
	CONCORDANT	DISCORDANT	CONCORDANT	DISCORDANT	CONCORDANT	DISCORDANT	CONCORDANT	DISCORDANT	CONCORDANT	DISCORDANT	CONCORDANT	DISCORDANT
Anterior Wall Pattern	4	2	1	11	5	12	5	1	12	0	15	2
Posterior Wall Pattern	2	1	3	1	9	0	2	1	1	3	3	6
Atypical Patterns	1	2	0	4	5	5	2	1	3	1	7	3

*A diphasic U or T wave was considered equivalent to an inverted U or T.

In cases of anterior wall infarction pattern this concordancy was less striking but still fairly definite. However, in the posterior wall infarction pattern there was a definite discordancy in direction in T and U, especially in the chest leads. Accordingly, an analysis was made to ascertain a possible relationship between the direction of U and the deviation of the S-T segment.

In cases of anterior wall infarction there was a definite discordancy in the chest leads between the U and the deviation of the S-T segment (Table IX). A similar, although less definite, discordancy occurred in the series of atypical infarction patterns. On the other hand, in the posterior wall infarction patterns there was a definite concordancy in the direction of the U wave and the deviation of the S-T segment; this was most striking in Lead CF_4 (Table IX).

THE EVOLUTION OF THE U WAVE

An attempt was made to correlate the evolution of the abnormal U waves with that of the S-T-T segment in all cases having serial tracings.

In 15 of the 17 cases of left ventricular preponderance with serial tracings the abnormal U waves persisted. In the other 2 the abnormal U waves became normal even though the T waves remained inverted.

The U waves changed in appearance in 4 of the 8 cases of the common type of intraventricular block which had serial curves. In 2 of these the inverted U waves became isoelectric although the T waves remained inverted. The changes in the U wave in the other 2 cases were also independent of the T wave change.

In 6 of the 17 cases of anterior wall infarction pattern with serial tracings the abnormal U wave became normal. In 5 of these the change occurred in Lead CF_2, and, in all but one, the T wave in the lead remained inverted. It is significant that no abnormal U waves were seen when the S-T deviation was marked and the T wave small, even when the S-T deviation persisted for 10 months after the clinical attack.

In 5 of the 8 cases of posterior wall infarction pattern with serial records the abnormal U wave became normal. In contrast to the anterior wall infarction pattern U-wave abnormalities were noted in the posterior wall pattern during the period when the T was small and the S-T markedly deviated.

In 7 of the 9 cases of atypical infarction patterns with serial tracings the abnormal U waves changed to normal. These alterations in the U waves occurred without regard to the S-T or T changes.

It appears, therefore, that the initial appearance of the abnormal U wave is related to inversion of the T wave and to the depression of S-T in all the patterns studied except in myocardial infarction. In the latter, U inversion appears related to T inversion in the anterior pattern and to S-T depression in the posterior pattern. The U-wave evolution is sometimes independent of the S-T-T segment evolution.

Rapid appearance and disappearance of abnormal U waves were observed in 2 cases of transitory coronary insufficiency (with angina pectoris). A similar transitory occurrence of inverted U waves can be seen in 4 of the cases recently illustrated by Twiss and Sokolow.[6] In none of these 6 cases were records taken with sufficient frequency to determine whether or not the U-wave abnormality paralleled the abnormalities in the S-T-T segment. These cases do illustrate, however, how rapidly an abnormal U wave may appear and disappear.

DISCUSSION

Our results indicate that there is a tendency for the occurrence of a definite U-wave pattern in the abnormal electrocardiogram, although in most the U wave is normal in appearance in all the leads. When U-wave abnormalities occur in left heart strain and in intraventricular block of the common type the pattern consists, usually, of inverted U waves in Leads I and CF_4 with isoelectric or normal, upright U waves in the other leads. In anterior wall

infarction abnormal (inverted and diphasic) U waves occur most frequently in both Leads CF_2 and CF_4 with an occasional similar abnormality in Lead I, while in posterior wall infarction inverted U waves occur most commonly in CF_4 alone, although there are other scattered abnormalities. In all the patterns studied there was a general concordancy of the direction of the abnormal U wave with the direction of the T wave except in the early stages of posterior wall infarction pattern where there was a marked discordancy. In posterior wall infarction a definite concordancy existed with the deviation of the S-T segment as in other abnormal states expect in anterior wall infarction.

It must be re-emphasized that in these conditions many more instances of normal than of abnormal U waves were found.

The relationship of the abnormal U wave in posterior wall infarction to the deviation of the S-T segment rather than to the direction of the T wave is further supported by the rarity of abnormal U waves in Lead III in this pattern, in which lead, classically, the S-T segment is elevated and the T wave inverted. If abnormality of the U wave were related to the T-wave inversion, numerous instances of inverted U waves should be present in Lead III. On the other hand, in anterior wall infarction in which the S-T segment is depressed and the T wave is upright in Lead III abnormal U waves are not found, because, in this pattern, the U-wave abnormality appears to depend upon the direction of the T wave.

No abnormal U waves were found in the absence of other abnormalities in the electrocardiogram studied. Therefore, at the present, there is not much diagnostic value in the recognition of U-wave patterns; however, a description of the latter in abnormal records, such as has been attempted in this report, might aid in explaining the nature of the fundamental processes leading to the pattern of the U wave. Furthermore this knowledge will help to identify instances of distortion of the T and P waves and lead to a better definition of the isoelectric level.

SUMMARY

1. In 1000 cases with diagnostic electrocardiographic patterns, 94 cases of abnormal U waves were found. The U-wave patterns in these 94 cases showed the following chief characteristics:

(a) In left heart strain and in intraventricular block of the common type the U-wave abnormalities consist of inverted U waves in Leads II and CF_4.

(b) In anterior wall infarction abnormal (inverted or diphasic) U waves are found in Leads CF_2 and CF_4 with occasional similar abnormality in Lead I.

(c) In posterior wall infarction inverted U waves are found most commonly in Lead CF_4.

(d) No abnormal U waves were found in right heart strain or in intraventricular block of the indeterminate S type.

2. A hitherto undescribed U-wave abnormality, a negative bowing of the T-P segment in Lead I, is discussed.

3. Instances of distortion of the T and P waves by large upright U waves

and the confusion caused by the presence of prominent U waves in records of auricular fibrillation are pointed out.

4. Evidence is presented relating the presence of abnormal U waves to abnormalities of the S-T-T segment. In left heart strain and in the common type of intraventricular block, there is usually concordancy in the direction of the T wave, S-T deviation and U wave direction. In posterior wall infarction there is concordancy of the deviation of the S-T segment and the direction of the U wave but discordancy between T and U. In anterior wall infarction the reverse is true.

5. In serial records the abnormal U wave may undergo an evolution independent of the changes in the S-T-T segment.

We wish to express our grateful appreciation to Doctors L. N. Katz and R. Langendorf for their helpful criticisms.

INACTIVATION OF VACCINIA VIRUS BY MILD ANTISEPTICS*†

WOLCOTT B. DUNHAM, M.D., AND WARD J. MACNEAL, M.D., NEW YORK CITY

LITTLE is known concerning the inactivating effect of antiseptics on the viruses. The present study was undertaken as one of a series to elucidate this subject. It seemed particularly desirable to investigate the action of antiseptics on the vaccinia virus, as this virus has been the most studied in other respects.

A number of reports have appeared on the effect of a wide variety of chemical and physical agents on the vaccinia virus. A partial summary of this literature is shown in outline form in Table I. It will be noted that this list contains few bacterial antiseptics and that in most of the investigations, the virus was exposed to the agent for an hour or more. In the tests to be described,

the vaccinia virus was exposed to the antiseptics for a period of only three minutes.

In a recent paper we[1] showed by means of chorio-allantoic inoculations that this virus is inactivated in 30 seconds by liquor antisepticus. The technic employed was rather time-consuming and it was not easy to make nearly simultaneous inoculations into a number of eggs. These difficulties were practically eliminated in the present study by injecting the mixtures of antiseptics and virus directly into the extra-embryonic fluids of the chick embryos. Two

advantages of this method are that a lot of 5 prepared eggs can be inoculated in half a minute and that the results tend to be remarkably uniform, apparently because the injurious effect of the needle puncture is slight. A disadvantage of this injection method is that localized pock lesions are seldom produced and hence one must, from time to time, test the virus by the chorio-allantoic method to be certain of its identity. Following inoculation into the extra-embryonic fluids, a generalized dissemination of the virus takes place and if the amount and activity of the inoculum are adequate, the embryo dies in two to four days. Death of the embryo is easily recognized by candling the eggs.

The virus suspension was prepared from incubated eggs which had died following injection of vaccinia virus CAEB, originally obtained from Doctor Joseph E. Smadel of the Rockefeller Institute. As a rule, the washed enveloping membrane of the yolk was used, but sometimes the tissue substance of the embryo itself and also the chorio-allantoic membrane were utilized. These tissues and membranes were ground with sand or glass granules and then mixed with Tyrode's solution, 1.5 c.c. for each yolk sac or chorio-allantois and 2 c.c. for each embryo body. The resulting suspension was centrifuged at 1,100 revolutions per minute for ten minutes. A pipette was then passed through the layer of yolk fat on top and the subjacent watery supernatant portion was withdrawn. This virus suspension was kept immersed in ice water until used. It was freshly prepared for each experiment and the virus strength was ascertained by titration of serial dilutions in each instance.

The eggs employed in the tests were incubated six to eight days, usually, seven days. Before use they were candled and only those with vigorous embryos were employed. These were marked to indicate the location of the embryo and the border of the air sac. The blunt end of the shell was treated with iodine and then alcohol and by means of a 2 millimeter dental bur, a hole was drilled through the shell without piercing the shell membrane. Several eggs thus prepared were placed in a holder with the embryo uppermost until the inoculations had been completed.

The test solutions were kept at room temperature before use. The virus suspension was at a temperature of about plus 4° C. In all instances nine parts of the test solution and one part of the virus suspension were vigorously mixed and allowed to stand for three minutes. At the end of this period the mixture was injected into the eggs directly or sometimes after dilution with sterile distilled water. The decision in regard to the dilution depended on the results of the toxicity tests previously reported by us[10] in which eggs were injected with antiseptics alone. Some mixtures were injected directly, others diluted tenfold and others a hundred-fold.

Just before the end of the three-minute exposure period, the shell openings of the prepared eggs were wiped with alcohol. The test mixture was then drawn into a tuberculin syringe fitted with a 2 inch, 20 gauge needle. The needle was passed through the hole in the egg shell and directed slightly upwards so that its point was about 12 millimeters below the mark on the shell indicating the location of the embryo, and 0.05 c.c. of the material was in-

jected. Examination of eggs inoculated in a similar manner with insoluble material has shown that the inoculum enters the allantoic cavity, or, occasionally, the amniotic cavity. After the injection, the needle was withdrawn without sidewise motion and the other eggs of the series were inoculated in rapid succession. Leakage through the puncture did not occur. The holes in the shells were then sealed with liquid adhesive and the eggs were returned to the incubator.

For each experiment the concentration of virus in the vaccinia suspension was determined by making ten-fold dilutions in series with distilled water and injecting each dilution into eggs. Ordinarily this series of dilutions extended from 10^{-1} to 10^{-8}. The titer of the original suspension was taken to be the highest dilution which killed half the embryos inoculated. The number of minimal lethal doses (M.L.D.) in 0.05 c.c. of the original suspension was taken to be the reciprocal of the titer. Thus where half the eggs were killed by inoculation of 0.05 c.c. of the 10^{-5} dilution, the titer of the original suspension was 10^{-5} and there were 100,000 M.L.D. in 0.05 c.c. of this original suspension. In no instances were tests of antiseptics considered significant unless the eggs received at least 10 M.L.D. of the virus. Beyond this minimum, the actual con-

[a]Prepared according to the officially revised formula, effective July 1, 1940.[11]

centration of virus in the suspension was found to be without effect on the outcome of the tests.

After inoculation the eggs were candled daily for six days. When an embryo appeared to be dead, as evidenced by loss of vascular markings, cloudiness of the embryonic region and increased passive mobility of the embryo, the egg was opened and examined. In the rare instances where the embryo was found malformed or had obviously died from hemorrhage, these facts were recorded and the egg was excluded from consideration in the determination of experimental results. Survival of the embryo for six days was accepted as evidence that the material injected contained less than one lethal dose of the active virus.

Each test was repeated at least three times, usually on different days with a newly prepared virus suspension in each instance. The results are summarized in Table II.

DISCUSSION

A certain amount of irregularity should be expected in biological experiments of this kind and we have not regarded the death of one embryo in a lot of five as of great significance. Occasionally an egg died as the result of obviously recognizable trauma and could therefore be excluded from consideration. Doubtless, an occasional death from unrecognized trauma also occurred. Furthermore, the virus suspension was not of entirely uniform composition. Although only the supernatant suspension, after centrifuging, was used, nevertheless this might well contain clumps and scattered particles of tissue elements which would furnish protection for contained virus elements and which might be irregularly distributed in the final suspension. Because of the very brief period of exposure for inactivation, three minutes, some irregularity due to this factor might well be anticipated. However, these irregularities have been so insignificant that they did not obscure the results.

As shown in Table II, 3 per cent phenol was moderately effective, while a 1 per cent solution failed to inactivate the virus. Tincture of iodine was effective when diluted to 1 per cent strength. This solution contained iodine in a concentration of 0.7 mg. per c.c. When the official tincture was diluted to 0.1 per cent strength, it was without effect. Bichloride of mercury was effective in a concentration of 1:1000, though a 1:10,000 solution failed to protect the embryos. When mixtures prepared from mild silver protein and virus were injected into eggs, 14 out of 15 of the embryos died. Copper sulfate, 1 per cent, showed some virucidal action. Potassium permanganate, 1:1000, failed to inactivate the virus under the conditions of the tests. A high degree of protection was afforded by a 70 per cent solution of propylene glycol in water, while a 50 per cent solution was without demonstrable effect. The concentration of propylene glycol in these mixtures was 63 per cent and 45 per cent respectively by volume, or 66 per cent and 47 per cent by weight. Full strength liquor antisepticus was effective, though in tests conducted with an 80 per cent solution, all but 1 of the eggs died. It was shown that the action of liquor antisepticus was not due to the 25 per cent alcohol or to the boric acid alone, as these agents when tested separately did not inactivate the virus.

A combination of the two in the proportion in which they are present in liquor antisepticus also failed to protect the embryos. Listerine, full strength, inactivated the virus, while an 80 per cent solution gave results similar to the same dilution of liquor antisepticus, N. F. VI. Commercial tincture of metaphen 1:200, diluted to one-quarter strength, inactivated the virus to such an extent that more than half the eggs survived. On the other hand, after inoculation with mixtures prepared from virus suspension and an aqueous solution of metaphen, 1:500, 13 of the 15 eggs died. Potassium mercuric iodide, 1:5000; merthiolate, 1:1000; and the commercial tincture of merthiolate, 1:1000, diluted to one-quarter strength, were without demonstrable effect. One egg survived out of 15 injected with mixtures containing 2 per cent mercurochrome and virus. Lysol, 2 per cent, inactivated the vaccinia virus in the 3-minute period. A 0.5 per cent solution gave some protection to the embryos, while all the eggs died which received mixtures containing 0.1 per cent lysol. A 1 per cent solution of amphyl inactivated the virus, whereas a 0.5 per cent solution was without appreciable effect.

The virus suspensions employed in the tests contained a considerable amount of protein, from 1 to 2 Gm. per 100 c.c. The mixtures of antiseptic and virus, therefore, contained 0.1 to 0.2 Gm. per 100 c.c. The action of certain of the antiseptics would undoubtedly be modified by the presence of this nonvirus protein. In nature, the viruses are associated with variable amounts of nonvirus protein, a fact which makes it desirable to test the action of an agent in the presence of both large and small amounts of protein. The protein content of the virus suspensions employed in the tests here described is probably comparable to that of most of the suspensions used in the tests reported by others and summarized in Table I, as the virus for almost all of those studies was obtained by emulsifying infected tissue or by collecting the lymph from vaccinia vesicles.

In a companion investigation,[12] we determined the action of antiseptics on the influenza virus by a similar technic, employing as the virus suspension extra-embryonic fluid from eggs which had died following inoculation with this virus. The protein content of this suspension was about 4.6 mg. per 100 c.c. The difference in concentration of nonvirus protein in the two sets of tests must be borne in mind if any attempt is made to derive from these results a comparison of the resistance of the influenza and vaccinia viruses to antiseptics.

SUMMARY

A number of antiseptics were tested for their effect on the vaccinia virus during a brief period of exposure. This was accomplished by preparing mixtures of the antiseptics and virus, allowing them to remain in contact for 3 minutes, diluting the mixture to a point where it would not be toxic for chick embryos and then injecting the material into embryonated eggs. Survival of the embryos indicated inactivation of the virus.

The following agents were effective in inactivating the vaccine virus in 3 minutes: phenol, 3 per cent; tincture of iodine, 1 per cent; bichloride of

mercury, 1:1000; propylene glycol, 70 per cent; liquor antisepticus, N. F. VI, undiluted; listerine, undiluted; tincture of metaphen, 1:200, diluted to one-quarter strength; lysol, 2 per cent; and amphyl, 1 per cent.

THE COMPARATIVE EFFECTIVENESS OF ARSENICAL COMPOUNDS AND SULFONAMIDE DRUGS AGAINST BACTERIAL INFECTIONS*

EDWIN E. OSGOOD, M.D., PORTLAND, OREGON

WITH THE TECHNICAL ASSISTANCE OF JANE M. ARMENTROUT, M.A.; DOROTHY M. ELLIS, B.A.; INEZ E. BROWNLEE, B.A.; AND JULIA JOSKI, M.A.

IN PREVIOUS publications it has been shown, experimentally by the technique of marrow culture,[1] and clinically in staphylococcic bacteriemias[2] and cases of subacute bacterial endocarditis,[3] that neoarsphenamine is more effective than drugs of the sulfonamide group against the *Staphylococcus aureus* and most strains of the *Streptococcus viridans*. The present study was undertaken to determine in cultures of living human marrow cells the comparative effectiveness of neoarsphenamine, many other arsenicals, and the four sulfonamide drugs in most common use against the *Staphylococcus aureus*, the *Streptococcus viridans*, and many species of bacteria not previously reported on.

*From the Department of Medicine and the Division of Experimental Medicine, University of Oregon Medical School, Portland, Oregon.

Aided by grants from Mr. John C. Higgins, The Department of Clinical Research, Abbott Laboratories, and The General Research Council of the Oregon State System of Higher Education. The drugs used in the experiments were supplied by the Abbott Laboratories, the Lederle Laboratories, the Winthrop Chemical Company, and E. R. Squibb and Sons.

Received for publication, Sept. 21, 1942.

Clinically and in animal experimentation, control of such variables as the size of the initial inoculation, the number and strain of organisms present, the concentration of the drug in the blood and tissues during therapy, the day of disease on which therapy is started, the natural resistance of the host, and the presence or absence of antibodies is difficult, if not impossible, to attain. By the use of the method of human marrow culture[4] these variables are controlled and quantitative studies are possible. In addition, it is possible to study the toxicity of the drugs to living human cells.

METHOD

About 10 c.c. of marrow obtained by sternal puncture[5] or leukemic blood were introduced into 25 c.c. of citrated balanced salt solution in a 50 c.c. vaccine vial. After centrifugation the buffy coat was transferred to another vial containing balanced salt solution, and a total nucleated cell count was done and the culture diluted to a final volume of 50 to 100 c.c. containing 100,000,000 to 200,000,000 nucleated cells. The medium consisted of 65 per cent balanced salt solution similar in composition to cerebrospinal fluid and 35 per cent human cord serum or ascitic fluid. To this was added the desired inoculum of the bacteria to be studied and, after mixing, pour plates for colony counts were made on a medium suitable for the growth of the organism. These represent the initial colony counts at 0 time in the tables. These cultures were mixed again, and equal volumes were transferred to a series of six to fifteen 30 c.c. vaccine vials. All manipulations were made with syringe and needle through 70 per cent alcohol on vaccine caps. To each of these vials, except the control, the desired concentration of the drug to be studied was added, and a volume of saline equal to that in which the drugs were dissolved was added to the control vial. The vials were then transferred to an incubator at 37° C., and at intervals pour plates for colony counts and stained smears were made. This technique insures that the cultures were identical in every respect except for the single variable of the drug introduced.

RESULTS

A total of 211 such experiments on 118 different strains representing 11 different species of bacteria was performed. All of the 211 such experiments were analyzed in drawing the conclusions in this paper concerning the relative effectiveness of different drugs. Unless colony counts in the same experiment at the same time for different drugs or different concentrations of the same drug differed by a ratio of 10:1 they were not regarded as significantly different. In Tables I to V the results of 5 of the 211 experiments are tabulated.

Note from Table I that against this small inoculum of *Staphylococcus aureus* arsenic trioxide and the pentavalent arsenicals, acetarsone, aldarsone and carbarsone, are almost totally ineffective; that sulfathiazole in a concentration of 10 mg. per 100 c.c. is about equally effective with sulfadiazine at twice this concentration; and that all of the trivalent organic arsenicals used in this experiment are much more effective in the concentrations employed than are either sulfathiazole or sulfadiazine. In this particular experiment neoarsphenamine in a concentration of 0.5 mg. per 100 c.c. is about equal in effectiveness to 0.33

Control	151	900,000,000	2,220,000,000	
Neoarsphenamine, 0.5 mg. per 100 c.c.	151	20	12	3
Arsphenamine, 0.3 mg. per 100 c.c.	151	600	400	60
Sulfarsphenamine, 0.33 mg. per 100 c.c.	151	360	100	35
Trisodarsen, 0.5 mg. per 100 c.c.	151	1,200	28,000	3,500
Mapharsen, 0.2 mg. per 100 c.c.	151	20	8	0
Mapharsen, 0.05 mg. per 100 c.c.	151	19,200	160,000,000	8,000,000,000
Clorarsen, 0.5 mg. per 100 c.c.	151	13	2	0
Clorarsen, 0.05 mg. per 100 c.c.	151	60,000	40,000,000	2,400,000,000
Sulfapyridine, 10 mg. per 100 c.c.	151	18,000,000	9,000,000,000	
Sulfathiazole, 10 mg. per 100 c.c.	151	80	13	5
Sulfadiazine, 10 mg. per 100 c.c.	151	100,000,000	5,000,000,000	

mg. per 100 c.c. of arsphenamine and only slightly superior in effectiveness to 0.33 mg. per 100 c.c. of mapharsen. It is far superior to 0.1 mg. per 100 c.c. of mapharsen and to 0.5 mg. per 100 c.c. of trisodarsen.

Note by comparison of Tables I and II that the strain of *Staphylococcus aureus* used in the experiment in Table II is far more susceptible to the action of all drugs than the strain employed in Table I. A larger inoculum is sterilized by concentrations of the drugs which failed to sterilize the strain used in Table I.

Note in Table II that in this experiment 0.5 mg. per 100 c.c. of neoarsphenamine, 0.2 mg. per 100 c.c. of mapharsen, 0.5 mg. per 100 c.c. of clorarsen, and 10 mg. per 100 c.c. of sulfathiazole are about equally effective; that 0.3 mg. per 100 c.c. of arsphenamine and 0.33 mg. per 100 c.c. of sulfarsphenamine are highly and equally effective; that 0.5 mg. per 100 c.c. of trisodarsen is definitely not as effective; and that mapharsen in a concentration one-tenth that of neoarsphenamine, which is about the ratio of their clinical doses, is not nearly as effective as neoarsphenamine but is more effective than an equal concentration of clorarsen. Also note how much less effective sulfapyridine and sulfadiazine are than is sulfathiazole in equal concentration.

Note in Table III that this strain of *Streptococcus viridans* is highly susceptible to the action of each of the trivalent organic arsenicals investigated but that clorarsen and mapharsen in one-tenth the concentration of neoarsphenamine are not nearly as effective.

Note in Table IV that the *Streptococcus hemolyticus* (beta hemolytic streptococcus, Lancefield group A) is far more susceptible to the action of the trivalent organic arsenicals than is the staphylococcus, since a larger inoculum is sterilized by the same concentrations of the drugs which failed to sterilize small inoculums of the Staphylococcus aureus. It is again evident in this experiment that trisodarsen in equal concentration is not as effective as neoarsphenamine; that mapharsen in one-tenth the concentration is not nearly as effective as neoarsphenamine; that the trivalent organic arsenicals are all far superior to the sulfonamide drugs; and that sulfathiazole is much the most effective of the sulfonamide drugs.

Note from a comparison of Tables IV and V that it is necessary to increase the initial inoculum to demonstrate the differences in effectiveness of the most effective drugs and to decrease the initial inoculum to demonstrate the differences in effectiveness of the least effective drugs.

Note in Table V the great susceptibility of this strain of *Streptococcus hemolyticus* to the trivalent organic arsenicals and that 0.5 mg. per 100 c.c. of neoarsphenamine is about equal in effectiveness to 0.25 mg. of mapharsen and 0.4 mg. per 100 c.c. of clorarsen; that 0.3 mg. per 100 c.c. of arsphenamine and 0.33 mg. per 100 c.c. of sulfarsphenamine are almost as effective but that one-tenth the concentration of mapharsen and clorarsen are not nearly as effective.

COMMENT

Analyses of the 211 experiments on the 118 strains representing 11 different species of bacteria were made. The pentavalent organic arsenicals studied and arsenic trioxide were almost totally ineffective when compared with effective concentrations of neoarsphenamine, either in the ratios of their clinical doses or in concentrations which would give an equal arsenic content. The pentavalent arsenicals studied included acetarsone, carbarsone, aldarsone, para-sulfonamindophenyl arsonic acid, tryparsamide, sodium cacodylate, and solarson. Only solarson seemed to be of any value at all, and this was far less effective than neoarsphenamine.

All of the trivalent organic arsenicals tested were highly effective against certain species of bacteria in concentrations of equal arsenic concentration to the effective range for neoarsphenamine previously determined to be 75 to 200 gammas (micrograms) per 100 c.c.,[6] corresponding to 0.375 to 0.1 mg. per 100 c.c. of neoarsphenamine. The trivalent organic arsenicals tested were neoarsphenamine, arsphenamine, sulfarsphenamine, trisodarsen, mapharsen, clorarsen, bismarsen, and silver arsphenamine. The latter two offered no advantages for clinical use, since they were relatively ineffective in comparison to the other arsenicals; so they were not studied very extensively.

The different species of bacteria and in some instances even different strains of the same species differed markedly in their susceptibility to the action of the drugs. When an organism was susceptible to the action of one of these arsenicals the same strain was always highly susceptible to the action of the other trivalent organic arsenicals when compared in doses having an equal arsenic content. When the organism was resistant to the action of one arsenical it was resistant to the action of the others as well, although this was not extensively investigated. While there were individual strain differences in susceptibility with each of the organisms tested, only with the *Streptococcus viridans* was there a sufficient difference to justify grouping these strains into separate categories. As pointed out in previous publications,[6] some strains of *Streptococcus viridans* respond to neoarsphenamine and not at all to the sulfonamide drugs, and these strains have arbitrarily been called "Group A." Other strains are susceptible both to the action of neoarsphenamine and to the sulfonamide drugs, and these have been arbitrarily called "Group B." Other strains have been susceptible to the action of the sulfonamide drugs and not to neoarsphenamine, and these have arbitrarily been called "Group C."

In Table VI, the response of the bacteria tested to the trivalent organic arsenicals is summarized. Note that the *Staphylococcus aureus*, *Streptococcus viridans* (Groups A and B), *Streptococcus hemolyticus* (betahemolytic streptococcus, Lancefield group A), *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, and *Hemophilus influenzae* are highly susceptible to the action of these drugs; whereas, the *Diplococcus pneumoniae*, *Escherichia coli*, *Eberthella typhosa*, *Salmonella schottmuelleri*, *Streptococcus viridans* (Group C), and *Streptococcus anhemolyticus* (gamma streptococcus) were almost totally unaffected by the same concentrations of these trivalent organic arsenicals. Most strains of the first six species of bacteria in Table VI were far more susceptible to the action of the trivalent arsenicals in the concentrations employed than they were to the usual concentrations of the sulfonamide drugs obtainable in the blood stream. *Neisseria gonorrhoeae*[7] and *Hemophilus influenzae*, however, were somewhat less susceptible to the action of the trivalent organic arsenicals than to sulfathiazole, sulfadiazine, and sulfapyridine, although they were more susceptible to the action of the trivalent arsenicals than to the action of sulfanilamide.

TABLE VI

SUMMARY OF THE RESPONSE OF BACTERIA TO TRIVALENT ORGANIC ARSENICALS

ARSENICALS EFFECTIVE	ARSENICALS INEFFECTIVE
Staphylococcus aureus	*Diplococcus pneumoniae*
Streptococcus viridans	*Escherichia coli*
Group A	*Eberthello typhosa*
Group B	*Salmonello schottmuelleri*
Streptococcus hemolyticus	*Streptococcus viridans*
Corynebacterium diphtheriae	Group C
Neisseria gonorrhoea	*Streptococcus anhemolyticus*
Hemophilus influenzae	

Against each of the organisms listed in Table VI, sulfathiazole was the most effective of the sulfonamide drugs and sulfanilamide was the least effective. All of these organisms, except the Group A *Streptococcus viridans*, showed some response to 10 mg. per 100 c.c. of sulfathiazole if small enough initial inoculums were used. Sulfapyridine was superior to sulfadiazine in equal concentration against most strains of all of the species in Table VI, except *Neisseria gonorrhoeae* and *Salmonella schottmuelleri* where sulfadiazine was as a rule superior to sulfapyridine.

While there were rather marked individual strain differences among organisms of the same species or group there was a very great variation in susceptibility of the different species of organisms to the trivalent organic arsenicals and to the sulfonamide drugs, as indicated by the maximum initial inoculums which could be sterilized.

Note from Table VII that the *Streptococcus hemolyticus* is the most susceptible organism to the action of the trivalent organic arsenicals and that the *Neisseria gonorrhoeae* is the most susceptible organism to the action of the sulfonamide drugs. For each group of drugs the organisms can be divided into five or six groups of markedly different susceptibilities.

Since six of the trivalent organic arsenicals tested were about equally effective in terms of equal arsenic content, it seemed desirable to calculate a thera-

TABLE VII

COMPARATIVE SUSCEPTIBILITY OF ORGANISMS TO NEOARSPHENAMINE AND SULFATHIAZOLE

NEOARSPHENAMINE, 0.5 MG. PER 100 C.C.		SULFATHIAZOLE, 5-10 MG. PER 100 C.C.

†Mg. per 100 Gm. (dose) ÷ Mg. per 100 c.c. (concentration).

peutic index to determine which of them should be most promising for clinical use. It has been previously determined[6] that the effective range of neoarsphenamine in clinical use is 0.375 to 1.00 mg. per 100 c.c. of blood corresponding to 75 to 200 gammas (micrograms) of arsenic per 100 c.c. Therefore, neoarsphenamine in a concentration of 0.5 mg. per 100 c.c. corresponding to 100 gammas of arsenic per 100 c.c. was used as a reference standard, and all experiments in which this concentration of neoarsphenamine was compared with one or more of the other five arsenicals were analyzed. From these data, Table VIII was prepared. The first vertical column in Table VIII lists the commonly used names of the six trivalent organic arsenicals which offer most promise in the treatment of bacterial infections. The second column gives the percentage of arsenic in the drug as it is supplied in ampoules, which is not always the percentage as it is calculated from the structural formula. The third column gives the concentration in milligrams per 100 c.c. of these drugs as commercially supplied which, from analysis of all of the experiments in which the drugs were compared, appeared to be equivalent to 0.5 mg. per 100 c.c. of neoarsphenamine. The fourth column gives the gammas (micrograms) of arsenic per 100 c.c. which correspond to the amount of drug listed in the third column. From examination of this

column it is apparent that the drugs are approximately equally effective in concentrations of equal arsenic content, with the exception of mapharsen which is slightly more effective than the others in terms of equal arsenic content. The fifth column is the maximum therapeutic dose in grams per 60 kilograms as given by J. E. Moore,[8] with the exception of clorarsen for which the dose is that of the largest ampoule commonly administered. Column 6 is the milligrams per 100 grams of body weight calculated from column 5. Column 7 is a therapeutic index, which was calculated by dividing column 6 by column 3. Column 8 is the same index transposed to a basis of "neoarsphenamine = 100" by dividing all of the values by 3 in column 7 and multiplying by 100. From this column it is readily apparent that in the ratios of the maximum therapeutic doses, neoarsphenamine is by far the most effective drug, sulfarsphenamine and arsphenamine next, trisodarsen less effective, and mapharsen and clorarsen much less effective. Similar indexes were calculated, based on the maximum toxic concentraton for marrow cells, and the maximum tolerated dose in grams per kilogram from the same table,[6] but these indexes showed an even greater superiority of neoarsphenamine and inferiority of mapharsen and clorarsen, so are not included in this article.

It is fortunate that neoarsphenamine proves to be the trivalent organic arsenical of choice in the therapy of bacterial infections, since a method of administration[6] to obtain an effective blood level for 50 per cent of the time over a period of 60 days has been developed from a series of blood arsenic determinations. It has been shown to be effective, if followed exactly, in several patients with staphylococcic bacteriemia and subacute bacterial endocarditis. It maintains a more uniform blood level than with the massive intravenous drip technique[9] over a much longer period and yet less arsenic is administered per unit period of time. It does, of course, introduce much more arsenic than the standard clinical group method of treating syphilis but it does not at any time raise the blood level nearly as high as the blood level rises after a single intravenous injection of 0.6 Gm. of neoarsphenamine in a 60 kilogram person.

Comparative analysis in a similar way of the equally effective concentrations of the sulfonamide drugs indicated that 5.0 mg. per 100 c.c. of sulfathiazole is approximately equal in effectiveness to 10 mg. per 100 c.c. of sulfapyridine, 20 mg. per 100 c.c. of sulfadiazine, and 30 mg. per 100 c.c. of sulfanilamide. There were marked individual strain variations in this susceptibility. It is apparent from this that sulfathiazole is the drug of choice among the sulfonamide drugs for therapy of infections due to the organisms listed in Table VI, except when toxic reactions, danger of meningitis, or the presence of meningitis indicates the use of sulfadiazine or sulfapyridine. Sulfanilamide was so much less effective than the other drugs that there seems to be little reason for using it further in the therapy of infections with an organism listed in Table VI. A more detailed presentation of the experimental evidence and the conclusions in regard to each of these organisms listed in Table VI will appear elsewhere in separate papers for each organism. It has already appeared for *Neisseria gonorrhoeae*.[7]

SUMMARY

Analysis of 211 experiments similar to those in Tables I to V on 118 strains of 11 different species of bacteria by the marrow culture technique comparing the

effectiveness of arsenical compounds and the four commonly used sulfonamide drugs is presented. This analysis indicates that in marrow cultures arsenic trioxide and the seven pentavalent organic arsenicals tested are ineffective against all of the species of bacteria studied in therapeutically feasible concentrations. All of the trivalent organic arsenicals ordinarily used in the therapy of syphilis are effective in marrow cultures against the six species of bacteria listed in column 1 of Table VI in concentrations corresponding to about 100 gammas of arsenic per 100 c.c. These trivalent organic arsenical compounds were almost completely ineffective in this concentration against the five species of organisms in column 2 of Table VI. The trivalent organic arsenicals at this concentration were more effective against most strains of the *Staphylococcus aureus, Streptococcus hemolyticus, Streptococcus viridans,* and *Corynebacterium diphtheriae* than the most effective of the sulfonamide drugs in concentrations of 5.0 to 10.0 mg. per 100 c.c. The trivalent organic arsenicals when compared in these concentrations were not as effective as sulfathiazole or sulfadiazine against the *Neisseria gonorrhoeae* and *Hemophilus influenzae* but were more effective than sulfanilamide. When effective at all, the equally effective concentrations of the six more commonly used trivalent organic arsenicals are shown in Table VIII, with the corresponding arsenic concentrations, maximum tolerated therapeutic doses, and a therapeutic index, indicating their relative promise of effectiveness in clinical use against bacterial infections. There was no consistent correlation between the effective concentrations of the trivalent arsenicals and the sulfonamide drugs tested. The equally effective concentrations among the sulfonamide drugs tested are sulfathiazole, 5.0 mg. per 100 c.c.; sulfapyridine, 10 mg. per 100 c.c.; sulfadiazine, 20 mg. per 100 c.c.; and sulfanilamide, 30 mg. per 100 c.c.

The bacteria tested showed marked species and strain differences in susceptibility to the action of the chemotherapeutic agents, as indicated by the size of the inoculum which could be sterilized by a given concentration, as shown in Table VII. The *Streptococcus hemolyticus,* as shown in Table VII, was the most susceptible organism to the action of the trivalent organic arsenicals, and the *Neisseria gonorrhoeae* was most susceptible to the action of the sulfonamide compounds.

CONCLUSIONS

Neoarsphenamine in a concentration which can be maintained 50 per cent of the time for 60 days clinically, if the directions for administration previously published[6] are followed exactly, deserves further trial in the therapy of subacute bacterial endocarditis and bacteriemias, endocarditis, or other serious infections due to the *Staphylococcus aureus, Streptococcus hemolyticus, Hemophilus influenzae, Neisseria gonorrhoeae,* and, possibly, as a local application in diphtheria. Sulfarsphenamine and arsphenamine are somewhat less and mapharsen and clorarsen are much less effective than neoarsphenamine when compared in concentrations attainable clinically.

Sulfathiazole would appear to be the drug of choice among the sulfonamide drugs now available for clinical use, with sulfadiazine to be substituted should sulfathiazole not be tolerated, and sulfapyridine or sulfadiazine to be used if meningitis is present or threatened.

THE EVALUATION OF ANTISEPTICS AND OTHER ANTI-INFECTIOUS AGENTS*

Ward J. MacNeal, M.D., and Nancy C. Farnsworth, B.S.
New York, N. Y.

COMMUNICABLE diseases and wound infections have assumed an increased interest because of the continuing extension of belligerent activity in the world and the measures for control of these disorders have again become of primary importance in medicine. One group of agents useful for this purpose includes those which may be employed to kill or inactivate disease-producing microbes or to restrict their activity so as to render them wholly or relatively harmless. Although not quite exact in application, the term antiseptics is used in a broad sense to designate the agents in this category and in this sense the germicides are included among the antiseptics.

Antimicrobic agents may be applied in various ways for the control of infectious diseases and, in general, they may be roughly grouped in three classes according to locus of action. Those which are applied to the microbe while it is still at a distance from its possible new victim are in the first category. Methods for sanitary disposal of human wastes, especially incineration, and the adequate protection of water and food supplies belong here. The boiling of drinking water, as in the preparation of tea in China, and the general chlorination of potable waters elsewhere rank high as hygienic measures. By the time the water is actually ingested by man the dangerously destructive high temperature or high concentration of chlorine is no longer present. These agents perform their beneficent function and then become diluted, chemically combined or otherwise vitiated before reaching the human body. If, however, they still retain their death-dealing properties at this time, the possible danger to man requires attention. Food sterilized by heat may be quite acceptable while that preserved with mercuric chloride or formaldehyde is not. Much of our knowledge of these protective measures belongs in the realm of rather ancient history[1] and the practical applications in sanitation have become routine. However, there still remain unsolved problems in this field and further exact information as to the existence and distribution of pathogenic agents outside the human body may lead to new practical advances. The evident distribution of the virus of poliomyelitis in sewage[2] and by con-

Received for publication, Sept. 24, 1942.

taminated insects[3] and the animal reservoirs of the virus of yellow fever[4] may be mentioned as items presenting new opportunities in this field.

In the second category may be placed those agents and procedures designed to protect from infection by their application to the surfaces of the human body, the skin, mucous membranes or recently contaminated open wounds. Carbolic acid, mercuric chloride, oxidizing agents and various alcoholic preparations are thus used for their local action as distinct from effect after absorption. The revolutionary advances in antiseptic and aseptic surgery which resulted from the epoch-making observations of Lister were initiated by the use of these agents and no adequately informed person could fail to acknowledge their real value when properly employed. These chemical substances are general protoplasmic poisons, able in some instances to destroy human tissues and even to kill the patient if administered internally in sufficient amounts. Hence they are used for their *local action* in such a way that the amount absorbed is too small to induce dangerous poisoning. This fundamental concept, very clearly understood in the preceding century, has become somewhat obscured by the teachings of some modern authors who have failed to distinguish clearly between the *local* protective action of an antiseptic and the effect of an antimicrobic agent *after absorption*. Garrod[5] has expressed his astonishment that this distinction has recently been so lightly disregarded. He has emphasized that local antiseptics help in cleansing the wound, deodorize it, prevent access of further infection and prevent transmission of infection to others; during the first two hours, when the infectious microbes are largely on the surface of a wound (contaminated wound) the local antiseptic may suffice to destroy them. The superficial tissues may be injured or even devitalized and the local leucocytes inactivated by this antiseptic procedure but this local destructive action is temporary and is a small price to pay in consideration of the control of the infectious agent. After a wound has been infected for several hours the microbes may have penetrated well beneath the surface where they cannot be effectively reached by the local antiseptic agent.

In determining the suitability of an antiseptic for local application, the experimental animal with a controlled wound should receive first consideration as a criterion. Russell and Falconer[6] made experimental wounds of the brain in rabbits and inoculated these wounds with streptococci, pneumococci or diphtheria bacilli and then, after lapse of an hour, they applied the antiseptic agent to be tested. Some local injury to the delicate brain tissues was to be expected. However, they succeeded in overcoming the infection and obtained complete recovery of their treated animals in contrast to the fatal outcome in untreated controls, by use of proflavine sulfate and 2:7 diaminoacridine hydrochloride. Such *in vivo* studies of antiseptics require considerable technical skill. Less exacting are many of the tests *in vitro*.

The official standard tests of the Food and Drugs Administration, U. S. Department of Agriculture[7] are relatively more simple. Here only one bacterial organism (*Staphylococcus aureus*) is used and its resistance is checked against carbolic acid. These tests are not considered adequate in all instances

as indicated by the following passage in the officially approved publication[7]: "The limitations of the phenol coefficient make it necessary in some cases to judge the germicidal preparation by other tests or by additional tests." These official procedures do afford evidence to decide whether or not the particular antiseptic is capable of killing or inhibiting the staphylococcus under the standard conditions and these procedures have been extensively employed in testing various antiseptic agents intended for local use.

The practice of using any one simple *in vitro* test as a criterion merits a few words of caution. The point of view is unfortunate. It is much better to make a more complete study of the antimicrobic agent to learn as fully as possible its properties, mode of action, limitations and its possible injurious effects upon vertebrate tissues and, from the results of such studies, to arrive at an estimate of its possibilities for good and harm. Actually one may not justly assume that the behavior of *Staphylococcus aureus* or of any other single species of organism toward an antimicrobic agent is a reliable measure of the behavior of other infectious agents. Furthermore, there is no justification for the assumption that any single technical procedure, *in vitro*, should be accepted as a final criterion for evaluating the antiseptic activity against even the single organism tested. A variation of technique may bring a new revelation. Therefore, new technical procedures should be welcomed as means of extending our knowledge but certainly they should not pretend to supersede the older "standard" methods. If one sets out to devise a single test to extol or to discredit any particular antiseptic, his task is not difficult provided other evidence can be excluded from consideration.

A brief consideration of some common antimicrobic agents may serve to illustrate the pitfalls and to indicate the many factors requiring attention. Mercuric chloride in a 1:1,000 dilution kills within one minute the staphylococcus in a not too heavy watery suspension. However, if the bacteria are suspended in blood or other albuminous fluid, this germicidal effect may be considerably delayed or even prevented. Furthermore, a new element of difficulty is thus encountered because it may not be easy to decide whether or not the microbe has been killed. Transfer to a medium containing ammonium sulfide or *inoculation into the living animal* may reveal continuing viability of the microbe although the ordinary transfer culture may remain inhibited by the associated trace of the germicide. Local tissue injury caused by mercuric chloride may ordinarily appear unimportant but if this agent is applied to large body surfaces for considerable periods it may be absorbed in sufficient amounts so as to induce severe nephritis and fatal anuria.

Iodine, especially in alcoholic solution, has been a favored local antiseptic for many years. It stains the superficial elements of the skin or mucous membrane or wound surfaces, if these are not too moist. The iodine remains for a time in the stained tissue, being more rapidly removed where there is abundant moisture and active circulation of blood. While the tissues are stained with iodine, the bacteria do not grow in them, but by removal of the iodine with thiosulfate one may often discover that the bacteria have not been exterminated

but are only in a dormant state. Hence in testing the germicidal action of iodine, the neglect of this step to inactivate the residual iodine may permit misleading results.

The soaps are only mildly antagonistic to ordinary bacteria but they have long held a favored place in the hygienic care of the skin, accessible mucous membranes and recent superficial wounds, largely because they aid in the mechanical removal of exfoliated epithelium, decomposing secretions, extraneous material and microbes. Practical medical and surgical experience has long justified the confidence placed in soaps. More recently it has been shown[8] that soaps possess remarkable potency to inactivate certain of the disease viruses, such as those which cause influenza, herpes and poliomyelitis. Obviously soaps are used for their local action, and their destructive effect upon blood[9] or internal tissue elements is of academic rather than practical importance in the antiseptic field.

One of the least dangerous of local antiseptics in general use is represented by liquor antisepticus of the National Formulary[10] and the many commercial preparations of similar composition. These are essentially mixtures of dilute alcohol, thymol, boric acid, essential oils and aromatic organic substances, sometimes with added flavoring and coloring matters. Liquor antisepticus is dispensed in a form so adjusted that it should be employed in the undiluted state and when employed as directed it is able to kill staphylococci promptly. Tests against the viruses[11] of cowpox and of influenza have recently shown that these pathogenic agents are quickly inactivated by liquor antisepticus in concentrations above 80 per cent. The germicidal power of this agent is lost when it is diluted to 50 per cent or more and tests performed with such dilutions are likely to mislead.

In the third category of anti-microbic agents we may consider those designed to act *after absorption,* upon microbes which have already penetrated to the internal medium of the living host, where they are surrounded by lymph or blood or by the protoplasm of living cells deep beneath the epithelial surfaces. Previous to the present century this category was made up almost exclusively of biological products, particularly the antisera produced by procedures of immunization, but in addition there were the purified chemicals extracted from cinchona bark, active against malarial parasites, and emetine, active against the dysenteric amoeba. The modern era of enthusiastic chemotherapy in this field began with the dyes, trypan-rot and trypan-blau, which could be given to mice in doses large enough to tint the entire body and, marvelous to tell, in doses adequate to cause, in the living mouse, the sudden and complete disappearance of trypanosomes from the blood, which had been swarming with these parasites before treatment. This achievement of the Ehrlich School was soon followed by the discovery of the arsphenamines, which could be given to rats in doses sufficient to cause a similar sudden disappearance of the spirochetes of relapsing fever previously swarming in the blood. Here, then, were examples of synthetic chemicals capable of selective destruction of certain microbes without, at the same time, killing the animal host. Subsequently various dye substances and many other synthetic chemicals have

been introduced and exploited. The enthusiastic reception of these agents has been due, in part at least, to their demonstrated actual efficiency. The most spectacular of recent antimicrobic chemotherapeutic agents are represented by the sulfonamides. It is possible to introduce sulfanilamide into mice by stomach tube or by parenteral injection in sufficient quantity to overcome an otherwise fatal infection with hemolytic streptococci and abundant clinical trial has demonstrated the value of sulfonamides in human infections with bacteria of this type and also of other types, especially gonococcus, pneumococcus, some types of staphylococcus, colon bacilli and sporogenic anaerobes. The continuing exploitation of new kinds of sulfonamides, which appear to be well-nigh inexhaustible in variety, affords opportunity for continued renewal of enthusiastic expectations and the febrile patient as well as his physician is often tempted to use one of these drugs even before the microbic cause of the fever has been ascertained, sometimes with disastrous result.

In testing these drugs, their administration to animals infected with the particular microbe was the first and still remains the basic and most reliable criterion of efficiency. Testtube methods are less expensive. One may determine the drug concentration necessary to prevent or restrict the growth of the particular bacteria in a culture medium such as broth, agar or citrated blood. When this is carefully done some interesting observations emerge, showing that biological study of this sort is not so simple as might at first be assumed. Prevention of bacterial growth has been found to depend not alone on the concentration of the drug in the medium but also to an important degree upon the size of the bacterial inoculum. Thus, when less than 1000 streptococci have been seeded, their growth has been completely suppressed by sulfanilamide in a concentration of 1 to 100,000, while with an inoculum of a million or more streptococci growth goes forward even in a drug concentration of 1 to 100. Furthermore, it has been found that the addition of a minute amount of para-amino-benzoic acid[12] to the culture medium serves to overcome the bacteriostatic influence of the sulfonamide and thus to permit growth even of a small inoculum. Other substances not yet precisely identified exhibit a similar influence.

Very ingenious technical methods have been employed by Fleming[13] to demonstrate and to test the antibacterial effects of the sulfonamides and of some other antiseptics. He uses slide cells in which citrated blood inoculated with variable small numbers of hemolytic streptococci and mixed with variable small amounts of drug are sealed in with sterile vaseline paper strips and incubated. Bacterial growth is grossly revealed by hemolysis and can be recorded by photography. When freshly prepared, the citrated blood contains living leucocytes and the conditions approximate those of the circulating blood. A small inoculum of less than ten streptococci may be completely suppressed by the natural citrated blood itself without addition of drug, whereas the same citrated blood after passage through cotton to remove the leucocytes will permit the streptococci to grow. Even more interesting, it was found that the addition of minute amounts of antiseptics, as, for example, carbolic acid 1 part in 700 of blood, serves to inhibit the natural anti-bacterial activity of the

phagocytic cells so that the minute inoculum of streptococci is permitted to grow and to hemolyze the blood while the control preparation without phenol shows no growth. Of course, when a sufficient strength of the phenol is used the growth is suppressed. Fleming has used this method to ascertain the effects in blood of very minute concentrations of various older antiseptics as well as of the newer sulfonamides and also to demonstrate the importance of the size of the inoculum and the variable behaviors of different kinds of bacteria. In another technical procedure, Fleming[13] has used solid agar in a Petri dish. Decimal dilutions of the bacterial culture are spread as broad streaks across the dish on the surface of the medium. Then a segment of the solid agar is cut out at one side of the dish and the resulting defect is filled with melted agar containing the drug to be tested, for example, 1 to 300 sulfanilamide. Diffusion of the drug extends from the insert into the original agar and tends to inhibit bacterial growth to a variable distance from the line of junction and by observation of this inhibition one may estimate the relative susceptibility or resistance of the particular bacterial strain to the drug and may also observe the importance of size of inoculum in determining the growth. This procedure is perhaps less laborious and exacting than the blood-slide culture method and it lends itself to the prompt testing of a culture recently isolated from the patient. These studies of Fleming help toward a better understanding of the action of chemotherapeutic agents in the blood stream and in the internal tissues, *after absorption*.

Somewhat analogous comparative studies of tissue toxicity and antibacterial influence have been carried out by other investigators. Osgood[14] has used *in vitro* tissue cultures of the cells of bone marrow to ascertain the quantity of drug required to inhibit bacterial growth in such cultures and the quantity of drug which will bring about destruction of the tissue cells, thus determining the effective antibacterial concentration and the effective tissue-toxicity concentration.

More recently Welch[9] and his associates have attempted to estimate toxicity of antibacterial agents by microscopic observation of phagocytic activity of leucocytes in diluted citrated blood to which the drug is added and to compare this tissue toxicity with the germicidal effect of the drug in a somewhat different dilute citrated blood.

We have used technical methods of Fleming and those of Welch in the study of various chemotherapeutic agents and have been able to confirm the observations of Fleming in regard to the sulfonamides. By the technic of Welch, however, it was found that azosulfamide is "toxic" in a 1:100 dilution and "not germicidal" in any concentration applicable by the prescribed technique and hence having an immeasurable "toxic index" above 40. Precisely analogous results were obtained with sodium sulfapyridine. Unfortunately, Welch and his associates have attempted to utilize this technical procedure, employing citrated blood, as a criterion for evaluation of antibacterial agents designed for *local use* on the body surfaces, an application which, as has been so clearly indicated by Garrod, is unscientific and likely to be misleading. In

our laboratory a test, by the technique of Welch, of such substances as lemon juice, whiskey, clear tea infusion, black coffee infusion, grapefruit juice, vinegar, tomato juice and baking soda, has shown that each of these agents exercises, according to this technical procedure, a powerful "toxic" inhibitory influence upon the phagocytic activity of leucocytes, while they are without demonstrable germicidal value.

The "toxicity" tests upon tissue cultures or upon fresh citrated blood have real value in the study of antibacterial agents acting *after absorption*. They are not, however, entirely adequate and reliable and may fail completely to disclose the important danger. The animal body includes different kinds of tissue elements which vary among themselves in their reactions to drugs. A concentration of alcohol too weak to influence the cells in a tissue culture or to inhibit leucocytes in citrated blood, may, nevertheless, when present in the circulating blood, cause alterations in the living nervous system which result in traffic accidents. Mercuric chloride in the blood in a concentration too small to influence phagocytosis may cause death from nephritis and uremia. Sulfamethylthiazole maintained in the blood at a level without demonstrable effect on leucocytes or tissue cultures may induce enduring paralysis. Sulfapyridine and sulfathiazole cause toxic injury, not by inhibiting phagocytosis, but by lesions in kidneys, gastrointestinal irritation, changes in bone marrow, myocardial injury[15] and other more obscure alterations. Deaths[16] directly ascribed to administration of the sulfonamides have recently been mentioned in medical publications. To those familiar with the methods of pharmacologic science, these comments will appear superfluous, but they seem to be needed at this time.

In our laboratory an attempt is being made to study tissue toxicity upon the *entire animal* by the relatively inexpensive procedure of injecting the drug into embryonated eggs.[17] The developing chick is a fairly standardized test object and the injected drug does not escape from the shell before hatching. Death of the embryo or survival and successful hatching are grossly evident. The method lends itself to comparative tests of antimicrobic agents alone, of these same agents mixed with infectious viruses or bacteria and of the infectious agents alone. It may prove useful.

SUMMARY

A distinction has been drawn between three groups of antimicrobial agents according to locus of action: (1) those acting apart from the human host called disinfectants; (2) those acting on the epithelial surfaces or upon superficial wounds, designated as antiseptics; and (3) those acting after absorption and classed as anti-infectious therapeutic agents, chemical and biological.

There is no single, easy and simple technical method of evaluating all these agents. The method of Ehrlich and Kolle, in which one administers large amounts to animals to ascertain the lethal dose and smaller amounts to infected animals to ascertain the therapeutic dose, approaches most nearly the ideal procedure. Unfortunately, not all microbes can be tested against drugs

in this way and when feasible the experiments are costly and the relationships sometimes so complex as to leave many questions unanswered. Various kinds of studies, including those *in vitro,* are, therefore, to be welcomed. We are opposed to the attempt to evaluate an anti-infectious agent on the basis of a single "standard" test and we must be on guard against the misleading result of a specially devised technique designed to extol or to condemn some particular agent. It is important also to recall that the causes of infectious diseases are many and varied in nature and that the drug effective against a spirochete may not control the anthrax bacillus, nor may the agent effective against the pneumococcus be assumed necessarily to be potent against the virus of small-pox or influenza. Especially unfortunate is the all too common assumption that an "antiseptic" must be considered worthless unless it may be relied upon to control all infectious agents in all concentrations. So far as we know, only incineration may be accorded this degree of efficiency with full confidence.

Biology is a science of complexities and the control of infectious diseases is a biological problem of the first order. We suggest therefore a broad approach to the study of anti-infectious agents, which welcomes all obtainable information from every reliable means of observation. One may thus determine the peculiar properties of the agent studied and may decide as to its place of usefulness, if any, in the control of infectious diseases. Too frequently the lack of this essential knowledge about an antiseptic and its applicability is the actual reason for failure in its use.

CONCLUSIONS

1. Anti-infectious agents acting on microbes at a distance from the host may be designated as disinfectants. Their toxicity for the human host may be unimportant when it is vitiated before they reach the host.

2. Agents applied to the body surfaces to oppose disease germs may be designated as antiseptics. Such agents should exert the desired local effect upon microbes and should be free from danger of serious poisoning, particularly after absorption. Animal experimentation, tests *in vitro* and clinical trial may contribute to the evaluation of such agents.

3. Antimicrobic substances acting after absorption belong to the category of chemical and biological therapeutic agents. The desired effect upon the microbe should be obtained by a drug concentration much less than that required to kill the animal host. Possible toxic effects may endanger particular organs or tissues and may sometimes be revealed only by animal experimentation or clinical trial.

4. It is possible to discredit or to extol a supposed antiseptic by employing a single selected test procedure to the exclusion of other evidence. Such misleading methods are not recommended.

5. Evaluation of an anti-infectious agent should be based upon all available knowledge of its properties obtainable by various procedures.

SPONTANEOUS RUPTURE OF THE SPLEEN DUE TO ACUTE LEUCEMIA or ACUTE LEUCEMIA DUE TO TRAUMA TO THE SPLEEN . . . WHICH?*

REPORT OF CASE AND REVIEW OF THE LITERATURE

A. S. RUBNITZ, M.D., OMAHA, NEB.

WITH THE COLLABORATION OF E. B. FLOERSCH, M.D., COUNCIL BLUFFS, IOWA

SPONTANEOUS rupture of the spleen in leucemia is a rare occurrence. A review of the literature revealed only seven such possible cases. Hannesfahr[1] (1923) states: "Unusually rare are spontaneous ruptures (of the spleen) in leucemia, of which there are only two cases in the literature, described by Rokitansky (1861)." Lange[2] (1928) mentions five cases from the literature and adds one of his own. Only one more case has been recorded since 1928, that of Neal[3] (1940).

As to the relation of trauma to leucemia, Olovson[4] (1939) collected 67 cases from the literature, and added two of his own, in which leucemia happened to occur in association with trauma to the spleen or to long bones. Six more cases have been reported since Olovson's paper was published: three by Yaguda and Rosenthal[5] (1939), two by Conzett[6] (1939) and one by Schau[7] (1939). There was also one case reported by Novikoff (1933) (cited by Forkner[8]) which Olovson failed to include in his tabulation, so that altogether about 76 such cases have been recorded. While it is true that in many of the reported cases the authors did not claim that trauma was responsible for the leucemia, yet a sizable number of cases have accumulated in the literature in which an etiologic relationship between the two seemed to exist.

The case presented here is of interest primarily because of the rarity of spontaneous rupture of the spleen in leucemia and secondarily because it brings up for consideration the question of traumatic leucemia.

CASE REPORT

H. B., white male, aged 24, milk delivery-man, was admitted to the Mercy Hospital on January 31, 1941. Chief complaints: weakness, abdominal cramps, nausea, profuse sweating and loss of weight. Family history was unimportant. Past history: at the age of 11 he was operated upon for appendicitis complicated by peritonitis. At the age of 13 he suffered a severe injury to the left side of the abdomen and the left flank, in a coasting accident; this was followed by hematuria. The physician who attended him at that time expressed the belief that both the left kidney and the spleen were ruptured. However, the hematuria quickly subsided, and the patient recovered from the accident in a relatively short time, seemingly suffering no ill effects subsequently.

History of present illness: On December 22, 1940, while the patient attempted to climb on the wagon in the course of his daily work, the horse started unexpectedly with a

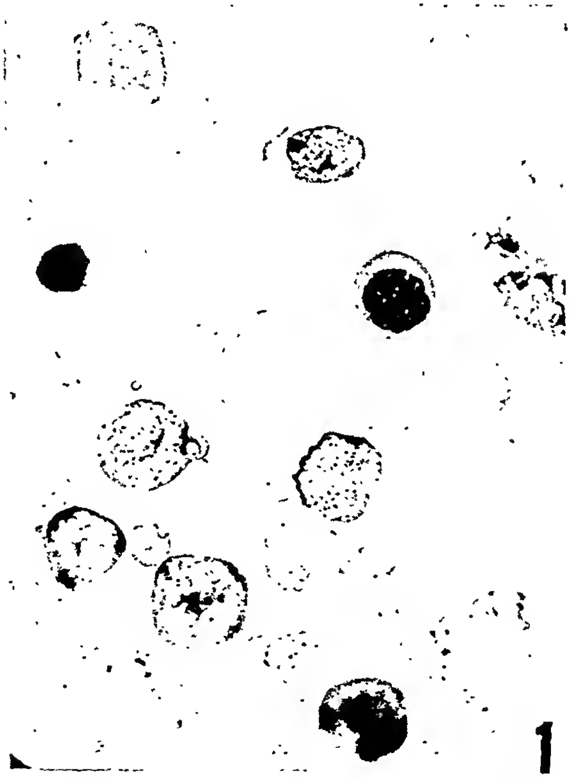
Received for publication, Sept. 28, 1942.

jerk; the patient missed the step and fell to the pavement twisting his body and the lower back. Upon examination at his home within three hours after the accident, skin abrasions over the right elbow were the only visible marks of injury. The objective findings were those of "lumbo-sacral sprain," and the patient was taped with adhesive. At the physician's office the following day, x-ray examination of the back and pelvis showed no fractures. Patient returned to work in a few days. About a week later he came down with the "flu" (as diagnosed by the attending physician). In a few days he again returned to work, but complained of being easily fatigued. On January 25, 1941, he reported for a physical examination, expressing the belief that he was suffering from "stomach ulcers." A routine blood count was done; the hemoglobin was 75 per cent; the erythrocytes numbered 4,200,000 and the leucocytes 9,800 per c.mm. Examination of the blood smears was not made. He was advised to go to the hospital for observation. This he refused to do at first, but consented to a few days later (Jan. 31).



1

Fig. 1.—Photomicrograph of blood smear taken on Feb. 13. ×930.

Upon entrance to the hospital, his temperature was 102° F.; there was abdominal tenderness and rigidity, and slight cervical adenopathy. The blood count was: Hgb. 14 grams; red blood cells, 4,640,000; white blood cells, 21,500. The differential count (as recorded by the technician) was: segmented neutrophiles 8 per cent; eosinophiles 1 per cent; lymphocytes (?) 91 per cent.

Progress in the Hospital.—The leucocyte count was 35,000 on Feb. 3. A careful study of the blood smears (A. S. R.) disclosed that almost 80 per cent of the leucocytes were promyelocytes, with occasional blast-cells. Most of the cells were oxydase positive. These findings were suggestive of acute leucemia. The clinical picture, however, did not warrant this diagnosis: there were no purpuric manifestations, no ulcerative lesions in the mouth, and but slight swelling in the cervical lymph glands. The patient's chief complaint was abdominal pain, not limited to any particular region. On account of overlying

muscle guard the spleen could not be palpated. The leucocyte count continued to rise: on Feb. 4 it was 40,700; on Feb. 7, 68,400, and on Feb. 11, 82,100. The appearance of the cells in the stained smears was frankly leucemic. In the last smear (see Figs. 1 and 2) 88 per cent of the leucocytes belonged to the young myelocytic series, mainly promyelocytes with occasional blast-cells and rare myelocytes. Nucleated red cells became very frequent. The red count on Feb. 11 was 3,600,000 and the hemoglobin 10.2 grams. A diagnosis of acute leucemia was made and a poor prognosis given. In spite of this the patient did not appear to be critically ill.

Fig. 2.—Photomicrograph of blood smear taken on Feb. 13. ×1700.

Other laboratory findings: (1) The urine contained a trace of albumin, isolated leucocytes and rare granular casts. (2) The blood N.P.N. was 36 mg. per cent and the creatinine 1.4 mg. per cent. (3) The hetrophile antibody reaction was negative. (4) The icterus index was 5. (5) The blood culture remained sterile at the end of 72 hours.

On Feb. 14 the patient, feeling unable to eat his breakfast, "forced down some food" and vomited shortly after. About 10 A.M. he became very restless and complained of weakness and pain in the precordium, requiring two hypodermic injections of morphine during the day for relief. He dozed for short intervals but continued to complain of precordial pain. His respirations became labored. At 6 P.M. his temperature rose to 104°, his pulse could not be counted accurately (recorded as 156?) and the respirations were 42 per min. He became irrational and involuntary. He died at 3 A.M., Feb. 15.

Autopsy was done at 8 A.M. Feb. 15. The body had been embalmed but the abdominal cavity had not been disturbed.

Important gross findings, as abstracted from the autopsy protocol: The left pleural cavity contained over one quart of thin blood-tinged fluid. The pericardial sac contained about 100 c.c. of bloody fluid. There were some ecchymotic areas in the epicardium near

the apex. The peritoneal cavity contained over one quart of clotted blood. A mass of confluent glands, the size of a hen's egg, was present in the mesentery of the ileum near the cecal juncture. The entire root of the mesentery was infiltrated with large glands, many of them the size of a walnut (see Fig. 4). The retroperitoneal lymph nodes along the aorta were greatly enlarged and formed a continuous chain extending from the pelvis to the diaphragm. The left kidney was rather small, weighing 110 grams; it was round

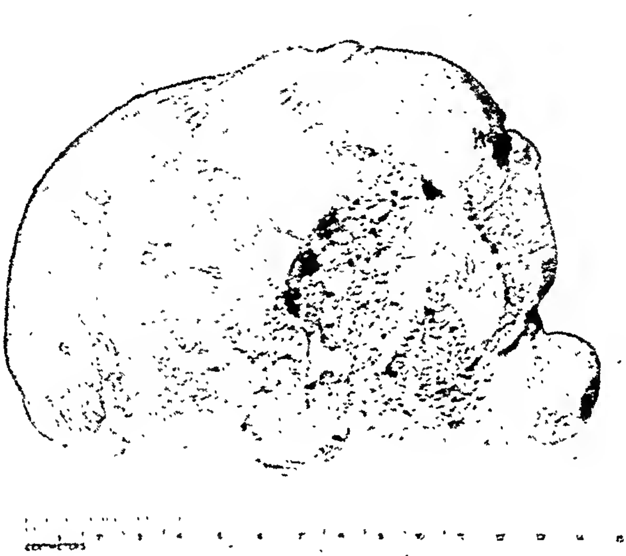


Fig. 3.—Photograph of ruptured spleen.

Fig. 4.—Photograph of mass of glands in the root of the mesentery.

and flat; the calices were distorted. The right kidney was of normal shape and quite large, weighing 330 grams. The spleen was enveloped in a mass of omentum. As the omentum was shelled off, a very soft, enlarged ruptured spleen was found. The rupture occurred almost through its middle, transverse to the long axis, and extended from the concave border nearly halfway across the width of the organ (see Fig. 3). The spleen weighed 420

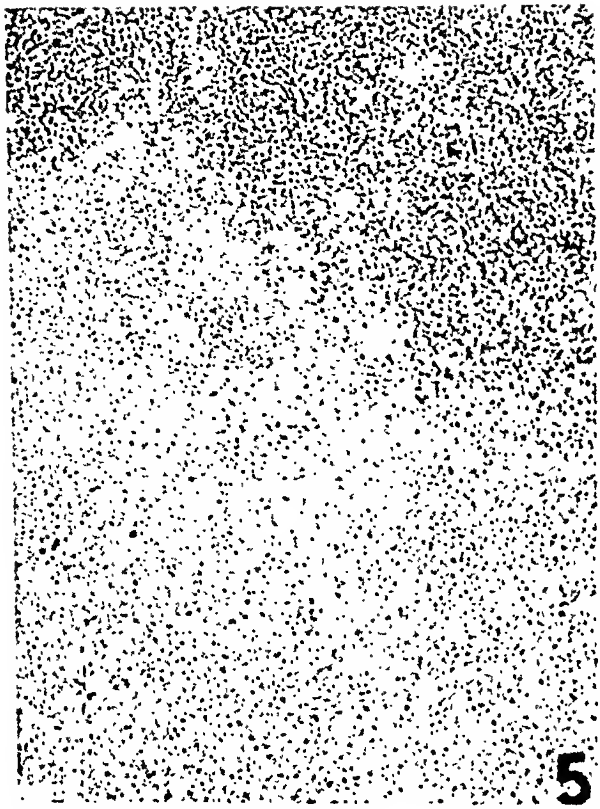

Fig. 5.—Photomicrograph of section of the spleen. ×140.

Fig. 6.—Photomicrograph of section of the liver. ×140.

grams; the tissue was unusually soft. On section, the color varied from reddish-brown to dark-chocolate. Many areas were cystic, the tissue being in a fluid state. The liver weighed 2390 grams. The cut surface was very soft. Both lungs had dark patches at the bases. On section, large edematous areas were present through the posterior portions of both lungs, especially in the lower lobes.

Summary of the gross anatomic findings: (1) Ruptured, degenerated spleen; (2) massive intraperitoneal hemorrhage; (3) swelling of the mesenteric and retroperitoneal lymph nodes; (4) left hydrothorax; (5) hemopericardium; (6) distortion and scarring of the left kidney and compensatory hypertrophy of the right kidney; (7) hypertrophy and degeneration of the liver; (8) pulmonary edema.

Important microscopic findings: Sections of the lymph nodes presented the usual histologic picture of leucemia. Frank leucemic changes were also evident in sections of the spleen, though here the process of necrosis overshadowed all other findings (see Fig. 5). Sections of the liver showed generalized parenchymal necrosis, fatty metamorphosis, and areas of leucemic infiltration. The latter were most pronounced in the interlobular connective tissue, around the ducts (see Fig. 6). Leucemic infiltration was also apparent in sections of the pancreas, kidneys, adrenals and lungs.

COMMENT ON CASE

It is difficult to evaluate the history of injury at the age of 13. According to the physician who attended him at that time, the patient had a hematuria which cleared up in a few days. Rupture of the spleen was suspected at first but the patient seemed to be in good physical condition and never manifested any evidence of internal hemorrhage. Moreover, by the time the hematuria disappeared, he seemed to have totally recovered from the effects of the injury.

The history of the accident six weeks before the patient's entry to the hospital permits a good deal of speculative reasoning.

One could assume that the patient suffered a subcapsular tear in the spleen, and that a hematoma was formed. The patient continued to complain of abdominal discomfort and developed fever and malaise which was diagnosed as "the flu." The hematoma could lead to increased tension within the spleen and cause degenerative changes in the pulp. All through the period of illness the degeneration might have continued to progress, and finally the organ might have ruptured from a trivial increase in pressure when the patient turned in bed or during the act of vomiting. This line of reasoning does not take into account the leucemic changes in the blood and tissues.

Again, one might speculate that the accident had nothing to do with the patient's illness. The onset of the illness might have happened to coincide with the time he returned to work after the accident. His complaints of malaise, weakness, anorexia and abdominal cramps were diagnosed as "the flu," a diagnosis often made at the onset of acute leucemia. The blood findings were not characteristically diagnostic at first but became more and more so as the disease progressed. simultaneously with the rapidly changing blood picture. and culminated in sudden spontaneous rupture.

A third combination could be rationalized: it might be assumed that the recent accident was not severe enough to produce rupture in a normal spleen. However, the accident suffered by the patient at the age of 13 might have produced a tear in the spleen which had healed. The scar formed in the line of healing might have given way during the last accident and brought about all

the sequelae of the first mentioned possibility. The fact that the spleen was highly degenerated made it impossible to demonstrate any preexisting lesions in this organ. From the appearance of the left kidney, however, one could surmise that the distortion in its shape was due to the coasting accident and that the spleen quite likely also suffered injury at that time.

GENERAL DISCUSSION

Spontaneous rupture of the spleen is invariably associated with preexisting disease of this organ. A normal spleen will not rupture unless it is subjected to violence of a considerable degree. Rupture of the spleen in the absence of obvious trauma is an indication that deep-seated degenerative and necrotic changes have taken place. Necroses of the spleen in leucemia are not uncommon. According to Lubarsch (cited by Schultz[9]), they occur in up to 50 per cent of the cases of myeloid leucemia, and are supposedly due to arterial thromboses. The damage of the arterial wall may be similar to that produced in periarteritis nodosa which leads to the formation of thrombi. According to Benda (cited by Schultz), the infiltration of the vascular wall with leucemic cells is a common occurrence in leucemia. Such infiltration within the walls favors formation of thrombi within the lumen. Another factor, initiating thrombus formation in leucemia, was pointed out by Hirschfild (cited by Schultz), as being the increased viscosity of leucemic blood. He explained the formation of thrombi in the corpora cavernosa on the same basis.

While the above-mentioned vascular changes produce or tend to produce necrotic changes in the spleen, such necroses are generally of a mild degree. Quite rare are the necroses which involve the greater part of the organ, as in the case recorded by Schultz. Even in his case the necrosis did not lead to rupture of the spleen. Our case is unique in that the degeneration of the spleen involved almost the entire organ. Such extreme necrosis has been recorded by Schtscherbatoff (cited by Friesleben[10]) in a patient who was recovering from a severe case of typhoid fever and who after a very light strain suddenly collapsed and died. Autopsy disclosed a transverse rupture of a totally disintegrated spleen.

The sequence of events in our case could be viewed from two different angles: (1) This was a case of rapidly progressing acute leucemia. The degenerative changes in the spleen paralleled the day-by-day hematologic changes, culminating in total disintegration and rupture of the organ. (2) This was primarily a case of degeneration of the spleen, initiated by a subcapsular hematoma of traumatic origin. The leucemic changes in the blood resulted from abnormal stimulation of the hematopoietic apparatus by the disintegrating spleen.

In a paper published under the title "Leukemia Following Trauma," Lewsen (1930)[11] collected sixty cases from the literature, including one case of his own. However, the evidence in twenty of the cases was not convincing and he tabulated only 40 of the cases (all of these are also included in Olovson's tabulation). The type of trauma was classified by Lewsen into three groups: (1) blow to long bones or ribs which may or may not result in a fracture; (2) blow in the region of the spleen, sometimes rupturing that organ, and (3) a general severe shaking. Lewsen concedes that trauma to

hematopoietic tissue does not always result in leucemia. He is of the opinion that leucemia would be produced only in individuals who have an inherent predisposition to this disease. He draws an analogy between traumatic leucemia and traumatic sarcoma, pointing out that trauma alone, without the individual predisposition, would hardly be sufficient cause for the production of either.

Analyzing his own tabulated cases, Olovson concludes that they could be divided into 3 groups: (1) those in which trauma leads to the discovery of an existing leucemia; (2) those where trauma causes an aggravation of an existing leucemia, and (3) those where trauma seemingly causes the leucemia. It is obvious that our attention would be centered principally on the cases of group three. Yet, even in these, according to Olovson, trauma could play but a minor role in the production of the disease, because traumata occur frequently whereas traumatic leucemia is a rare occurrence. He is of the opinion that trauma may constitute the exciting factor in a person predisposed to leucemia.

Yuguda and Rosenthal are still more outspoken in their view that trauma could not be the sole factor in the production of leucemia. These authors believe "that trauma initiates leucemia in a person with a preexisting tendency to the disease. The injury upsets the fine hematopoietic balance which has maintained the leucemia in its latent state and causes a more rapid progression of the process with development of frank symptoms of leucemia."

In the main all the above authors agree that trauma to hematopoietic tissue by itself could not be considered sufficient cause to produce leucemia. They all believe that trauma plays the role of a precipitating factor, in an individual who has an inherent tendency to the disease.

Mention may be made here that the problem of trauma and leucemia also attracted attention in veterinary medicine. Cases of leucemia following trauma have been observed in a sheep, a horse, and in dogs, as reported by Weber, Wirth, Share-Jones and Jarmai (all these authors are cited by Olovson). Jarmai conducted a series of experiments on dogs in which he traumatized the spleen by an open operation. However, all the experiments resulted in failure to produce any leucemic changes in the animals.

The problem of trauma and leucemia is of special importance from the medicolegal standpoint. In Olovson's series, 19 of the cases have been scrutinized by insurance commissions and 12 were granted compensation. This presumably implies that on the surface, at least, a cause-and-effect relationship seemingly was present in the 12 cases. Furthermore, we should be mindful of the fact that insurance companies will often tend toward leniency in settling an accident claim, particularly where it is known that the individual's illness dated to the accident. None-the-less, insurance companies will not grant compensation unless the case merits consideration.

In order that a case of leucemia could justly be considered as one due to trauma and qualify for compensation, the following criteria were set up by Liniger (cited by Yaguda and Rosenthal):

1. The injured individual must have been well and feeling capable of work up to the time of the accident.

2. A suitably severe accident must have taken place, with the essential subjective and objective signs of injury.

3. The time at which the development of sickness starts and that of the accident must bear a relation, that is, there must be bridging symptoms.

Olovson's criteria are:

1. Good health and absence of disease-symptoms before the trauma.

2. A free interval between the trauma and the first appearance of the symptoms.

3. Leucemia of the myeloid type.

Points 1 in both sets of criteria are essentially identical. Liniger's point 2 does not need any elaboration. Both Liniger's point 3 and Olovson's point 2 deal with the time-element between the trauma and the first manifestations of the disease. However, each one of these authors expresses a different conception and stresses a different point. Both these points merit consideration and can best be emphasized by illustrative cases:

Illustration 1. (Case 2 of Conzette.) A middle-aged woman suffered an intertrochanteric fracture. Upon admission to the hospital, immediately after the accident, her leucocyte count was 188,000 and the blood smear showed the characteristics of chronic myeloid leucemia. The spleen was decidedly enlarged.

Illustration 2. (Case 1 of Olovson.) A 27-year-old male suffered fracture of the leg. The fracture healed and the patient was seemingly in very good health for over 20 months, when he developed pain and swelling at the site of the fracture. At this time his leucocyte count was 347,000 and the blood smear was characteristic of chronic myeloid leucemia.

Of these two illustrations, the first depicts an instance where a leucemic individual suffered a fracture. Olovson's point 2, calling for a free interval between the trauma and the first appearance of the leucemic symptoms, excludes this case from the category of traumatic leucemias, and the case well illustrates the soundness of that point. In the second illustrative case an interval of over 20 months elapsed between the injury and the appearance of leucemic symptoms. There was a total lack of bridging symptoms. Liniger's point 3 would tend to exclude this case from the category of traumatic leucemias.

That the leucemia must be of the myeloid type in order to be considered as of traumatic origin (as advocated by Olovson's point 3) is a strongly debatable question. Nearly all of Olovson's 69 tabulated cases were leucemias of the myeloid type (only 3 of the cases were lymphatic leucemias). These figures, perhaps, were partly responsible for that contention. However, this statistical preponderance of myeloid leucemias is lessened by the fact that out of the 7 cases not included in Olovson's tables, 4 were lymphatic leucemias (one case of Novikoff, one of Schau, one of Yaguda and Rosenthal, and one of Conzette). Discarding the statistical reason for that contention, we come to the more valid reason, namely, that if traumatic leucemia is produced by injury to long bones or to the spleen the implication would be that such injury upsets the myelopoietic tissue, hence leucemia of the myeloid variety only could result. This reasoning is based on the assumption that lymphatic leucemia has its origin in histo-biologic disturbances of the lymphocytic apparatus, whereas myeloid leucemia has its origin in the myeloid tissue. While it is

true that this strict subdivision could be visualized in chronic leucemias, the site of the hematopoietic disturbance in acute leucemias is not as a rule so clearly delimited. The process of metaplasia is a common characteristic of acute leucemia, and tissues which are in no way concerned with the function of hematopoiesis in postnatal life generally revert to their embryonal state and resume such a function, producing abnormal leucocytes of every variety; hence the difficulty in most instances to classify acute leucemias according to cell types. Incidentally, an analysis of all the reported cases of traumatic leucemia reveals that the most authentic cases are those in which acute leucemia resulted from the trauma.

The most weighty argument, however, against Olovson's point 3 is the case reported by Schau:

> An 18-year-old boy was hit in the left side of the abdomen, playing football. At the hospital, rupture of the spleen was suspected but the patient was treated conservatively. The leucocyte count was 9,000. About 7 weeks later the patient was readmitted with a clinical and hematologic picture of frank leucemia; the leucemia, according to the author, was lymphatic in type. Autopsy disclosed an old tear in the spleen.

According to advocated criteria, this case is an excellent example of traumatic leucemia, though it was not one of the myeloid variety.

From the foregoing discussion one may deduct that the criteria advanced by Liniger and by Olovson for the medicolegal evaluation of a case of traumatic leucemia are logical and sound, except point 3 of Olovson in which the author insists that the leucemia must be of the myeloid type.

It might be of interest to mention here that a monetary settlement was granted by the insurance company in our case.

SUMMARY

A rapidly progressing case of acute leucemia is reported. The rapidity of the progress of the disease was most noticeable in the blood changes, whereas clinically the patient did not appear to be critically ill until almost the end. On the fifteenth day of the patient's stay in the hospital his condition suddenly changed for the worse, and after a stormy 18 hour period he expired. Autopsy disclosed a massive intraperitoneal hemorrhage resulting from a ruptured spleen. The spleen was degenerated throughout. The degeneration was attributed to leucemic changes in the organ. However, two previous episodes in the patient's history could have accounted for some damage to his spleen: (1) about 11 years previously the patient was in a coasting accident suffering injury to the left kidney and presumably also to the spleen, and (2) about 8 weeks before his death the patient fell on the pavement, spraining his back and "wrenching" his body. That the patient actually suffered serious injury to the spleen in either of these accidents is only conjectural. Because of the extreme disintegration of the spleen, histologic evidence could not be relied upon to prove or disprove that the organ had suffered injury in the past. It is conceivable that at the time of the coasting accident a tear in the spleen had been produced and that this healed by scar formation. Furthermore, it is conceivable that during the last accident the pulp gave way in the line of the old scar and a subcapsular hematoma was formed, leading to sub-

sequent "spontaneous" rupture. It is granted that no absolute proof exists that the spleen was severely injured in either of the two episodes; yet, because of the fact that the history of the last accident was so intimately tied up with the patient's last illness and because of the patient's persistent complaints of abdominal pain throughout the period of the illness, credence may be given to the view that the degenerative changes in the spleen set in before the hematologic changes were noticeable. Since a number of leucemic cases are recorded in the literature in which trauma to the long bones or to the spleen preceded the leucemic changes, some authors express the belief that leucemia may be precipitated by trauma in susceptible individuals. If we accept the dictum that there is such an entity as traumatic leucemia, our case would fall into that classification, and the entire clinical behavior of the patient, from the day of the accident to the hour of the fatal termination, would appear to be in logical sequence.

The question of the possible causal relationship between the trauma and leucemia is of interest from two angles: (1) the theoretical soundness of the view that leucemia could be caused by trauma, and (2) the medicolegal side of the problem, i.e., should an employer or insurer be held liable for the leucemia in a case where leucemia follows trauma. An attempt has been made in this paper to analyze both phases of the question and to bring out the more authoritative statements and data from the literature regarding this question.

CONCLUSIONS

1. Spontaneous rupture of the spleen in a case of acute leucemia is reported.
2. Since there was a history of an accident suffered by the patient about 6 weeks before the leucemia was established, the case is also discussed as one of possible traumatic leucemia.
3. The literature on the subject of traumatic leucemia is reviewed.
4. The medicolegal criteria recommended for the acceptance of a case as one of traumatic leucemia are scrutinized.

CLINICAL CHEMISTRY

THE EFFECT OF DIATHERMY ON BRAIN METABOLISM: CHANGES PRODUCED ON THE SUGAR, LACTIC ACID, AND pH OF THE ARTERIAL AND VENOUS BLOOD OF THE BRAIN IN PARETIC PATIENTS

JOSEPH M. LOONEY, M.D., AND EMBRIE J. BORKOVIC, M.D., WORCESTER, MASS.

IN A recent communication[1] we pointed out that during diathermy therapy in our patients the oxygen A-V difference showed a fall rather than a rise as obtained by Himwich and his co-workers.[2] In this paper we are reporting the results of hyperthermia on the sugar, lactic acid, and pH of arterial and venous blood. The same procedure for obtaining blood samples was followed as given in the previous paper.[1]

The blood sugar was determined by the method of Folin,[3] the lactic acid by the method of Edwards,[4] and the pH of the whole blood at 38° C. by the glass electrode and an electron tube potentiometer built according to the method of Stadie.[5] All determinations except the blood sugar were made in duplicate. The means and standard deviations for the different variables for the three periods of observations are given in Table I. Each value represents the results obtained from twenty-one separate experiments.

Both the arterial and venous blood sugar levels showed a fall during the period in which the temperature was rising and then an increase to a higher level than the control reading. The decreases in sugar for both venous and arterial blood, as well as the subsequent increases, were statistically highly significant. The difference between the final and initial readings, however, was not significant for either the arterial or the venous blood. The difference between arterial and venous blood sugar increased from a mean of 7.3 mg. for the first reading to 11.0 mg. for the final reading. This change was not statistically significant, as the P value calculated for this change is 0.32, which indicates that this change could occur by chance 32 times in every 100 trials.

The lactic acid levels in both arterial and venous blood showed a slight decrease during the period of elevated temperature. The decrease was greater in the arterial blood, with a fall from 14.22 to 11.97 mg., than in the venous blood, which decreased from 13.36 to 12.15 mg. and then rose to 12.61 mg. As a result of the difference in the degree of change, the final level of lactic acid in venous blood became higher than that of the arterial blood. Although these changes were not statistically significant, the trend is important when considered in connection with the changes which occurred in the oxygen con-

Lactic acid (mg. per 100 c.c.)	Arterial	14.22	4.48	12.39	5.08	11.97	4.26
	Venous	13.36	3.88	12.15	5.65	12.61	4.20
	A-V	0.86	2.61	0.24	5.54	-0.64	2.32
pH	Arterial	7.462	0.066	7.514	0.077	7.497	0.072
	Venous	7.398	0.059	7.459	0.068	7.465	0.087
	A-V	0.064	0.033	0.055	0.026	0.037	0.023

*First reading immediately before diathermy; second reading when temperatures reached 106° F., approximately two and one-half hours later; third reading, after three to *four* hours' fever at 106° F.

sumption and sugar metabolism. In our previous paper[1] it was shown that the oxygen consumed decreased as the temperature was maintained at the higher level. This would indicate that the rate of combustion in the brain did not increase with the temperature. The slight increase in utilization of sugar could be explained, at least in part, by the transformation of some of the sugar to lactic acid. The values of lactic acid in the arterial and venous blood of the brain for the first two readings indicate the utilization of some lactic acid by the brain tissues during this period. During the last period, however, there is a reversal, and a production of lactic acid occurs, the venous level being higher than the arterial level.

The pH of the blood showed a significant rise during the period of elevated temperature in both venous and arterial blood. In the arterial blood there was an increase from 7.462 ± 0.0148 to 7.514 ± 0.0172 and then a drop to 7.497 ± 0.0162. The difference between the first and last readings was not statistically significant. In the venous blood the changes from the initial reading, 7.398 ± 0.0132 to 7.459 ± 0.0153 for the second reading and 7.465 ± 0.0152 for the final reading, were highly significant. The values of Fisher's P for the differences between the readings were 0.0023 in the first case and 0.0008 in the second.

The change in the arterial-venous differences in the pH values was highly significant (P = 0.002) between the initial reading of 0.064 ± 0.0072 and the final reading 0.037 ± 0.0051 but was not significant between the first and second readings. With the increase in temperature the difference between venous and arterial blood became smaller, the greatest change occurring between the second and the third readings. The fall in the A-V difference between these readings was entirely accounted for by the fall in the pH of the arterial blood.

DISCUSSION

The elevation in blood sugar has been noted by previous investigators.[6, 7] Our results agree with those of Hench,[6] that the elevation is not due to blood concentration, for we obtained a 40 per cent increase in sugar from the lowest to the highest readings and only a 7.5 per cent hemoconcentration on the basis of the hematocrit readings, or a 14.8 per cent increase on the basis of the total protein levels.

Despite this marked increase in the concentration of sugar in the cerebral circulation, there was no increase in the utilization of sugar. The slight increase in A-V difference noted during the third period could be accounted for, in part, by conversion to lactic acid. These results confirm our previous findings[1] that hyperthermia resulting from diathermy therapy does not increase the rate of brain metabolism.

Our findings also lend support to the view that under certain conditions the brain does utilize lactic acid. However, when the temperature is elevated, lactic acid is produced. This may be due to an interference with the delicately balanced enzyme systems as the result of the increased temperature.

The alkalosis produced (amounting to 0.07 pH units in the venous blood and 0.03 pH units in the arterial blood) is due to the loss of carbon dioxide and is not as marked as that reported by Bischoff and co-workers.[7] These

investigators found increases in plasma pH of 0.12, 0.09, 0.26, and 0.04 in four cases. Cullen, Weir, and Cook[9] in a recent paper indicate pH changes of 2.0 pH units. This value is so high that it seems likely that an error has been made in reporting and that the change should be 0.2 pH units. Their results were obtained on blood taken from the arm, and therefore conclusions as to changes which occur in the cerebral circulation are not warranted.

In the case of one of the patients who died following treatment, the blood sugar showed wide fluctuations in level but no difference between the arterial and venous readings, which were 211 and 211, 95 and 94, and 155 and 154 mg. per 100 c.c. One patient showed a remarkable increase in arterial blood sugar with the following values: 98, 109, and 290 mg. per 100 c.c. It would appear that in this case the continued elevation of temperature for the three-hour interval at 106° F. had caused a marked stimulation of the adrenal mechanism and a release of sugar from the glycogen deposits in the liver. In his second treatment the patient showed an elevation from 95 to 164 mg. Another patient showed a rise from 98 to 190 mg. It is evident that although slight increases in sugar are found in all patients during periods of temperature elevation, very marked changes are the exception. The high mean values for sugar found in the control period are due to the inclusion of two men with abnormally high fasting values. During the period in which active heating of the body was taking place, in fourteen of twenty-one tests the blood sugar fell. This fall also occurred in the two cases that had high initial values, in the first instance from 211 to 95 mg. per 100 c.c., and in the second, from 176 to 78 mg. per 100 c.c. This initial fall in sugar has not, to our knowledge, been reported before.

TABLE II

COEFFICIENTS AND PROBABILITIES FOR CORRELATIONS BETWEEN TEMPERATURE AND INDIVIDUAL VARIABLES

CHANGE IN TEMPERATURE VS.	NO. OF READINGS	R	P
Change in venous blood sugar	38	0.7187	< .01
Change in arterial blood sugar	37	0.5371	< .01
Change in total protein	38	−0.1628	
Change in blood hematocrit	32	−0.0979	
Change in specific gravity	37	−0.2457	
Change in venous lactic acid	38	−0.1516	
Change in arterial lactic acid	38	−0.1119	
Change in venous pH	36	0.5109	< .01
Change in arterial pH	36	0.4725	< .01

The correlations between change in temperature and the other variables are shown in Table II. It will be noted that only those between temperature and sugar and temperature and pH can be considered significant. Contrary to expectation, the correlations for total protein, blood hematocrit, and specific gravity are very low. Incidentally, the correlation between specific gravity and total protein is also low, as pointed out in a paper published recently.[10]

SUMMARY

The changes produced in cerebral blood sugar, lactic acid, and pH by elevation of temperature through diathermy in twelve patients receiving dia-

thermy treatments are given. There was a slight but not significant increase in sugar utilization and a significant increase in pH. The lactic acid A-V difference becomes reversed so that during the period of continued temperature elevation, lactic acid is produced. This would explain, in part, the slight increase in the A-V difference for blood sugar. The findings confirm those previously reported, that there is no increase in brain metabolism during diathermy.

CIRRHOSIS OF THE LIVER: THE LIPOTROPIC ACTION OF PARENTERALLY ADMINISTERED AMINO ACIDS

I. Donald Fagin,* M.D., Melville Sahyun,† Ph.D., and Ralph W. Pagel,* M.D.
Detroit, Mich.

In a recent publication[1] an investigation of the possible therapeutic effects of intravenously administered amino acids‡ in five patients with cirrhosis of the liver was reported. Briefly, the results were (1) subjective improvement of great or moderate degree in four of the five patients during the one month period when the amino acids were used; (2) shrinkage in size of the liver and spleen in all patients in whom these organs were enlarged; (3) disappearance of peripheral edema; (4) indications of improvement in hepatic function, as gauged by hippuric acid synthesis and glucose tolerance tests in all cases, and improvement in bromsulfalein excretion in one case. On the basis of published experimental data it was postulated that the decrease in size of the liver was

Received for publication, Dec. 14, 1942.

due to the resorption of fat through the lipotropic action of the amino acids. The decrease in splenic size was interpreted as resulting from a decongestion secondary to improved portal circulation.

This report presents data derived from analyses for total lipid and total nitrogen content of the livers of three groups of patients: (1) those who died with cirrhosis of the liver but received amino acid therapy; (2) patients who died with cirrhosis of the liver who did not receive amino acid therapy; and (3) patients who died from other causes without cirrhosis of the liver. The value of this study arises through an opportunity to compare data collected from the chemical study of human livers with those published from similar studies in experimental animals.

Of the five patients who received parenteral amino acids, three (G. R., A. G., and P. W.*) evidenced sufficient clinical improvement to warrant discharge from the hospital. The remaining two patients (J. R. and G. B.*) maintained a clinical plateau for two and one-half and three and one-half months, respectively, following the month of amino acid administration, then entered a rapid and progressive downhill course and died in the hospital. All five patients exhibited a very slight increase in liver size when the administration of amino acids was discontinued; however, in no case did the liver return to its original degree of enlargement, presumably because the patients were maintained on an adequate diet.

To the patients studied and reported, we have added E. C., a patient with chronic alcoholism and advanced "decompensated" cirrhosis of the liver, who died two months after having received amino acids. Autopsies were performed on the patients who died in the hospital (G. B., J. R., and E. C.), and the livers grossly and microscopically exhibited the characteristic pathologic features of portal cirrhosis of the Laënnec or "alcoholic" type. All three patients had a background of chronic alcoholism.

MATERIAL AND METHOD

Formalin-fixed specimens of liver obtained at autopsy from three groups of patients were analyzed for total fat and total nitrogen content; the duration of formalin fixation of the specimens varied from a few days to eighteen months.

Group I consisted of the three patients described above who had cirrhosis of the liver and chronic alcoholism and received parenteral amino acids for three weeks (E. C.) or one month (J. R. and G. B.) during their course.

Group II consisted of patients who had cirrhosis of the liver and chronic alcoholism but had not received amino acids. We reviewed our autopsy protocols for the eighteen-month period prior to this study and found four such cases. No cases with cirrhosis of the liver and chronic alcoholism other than the seven included in Group I and II came to autopsy during this eighteen-month period.

Group III consisted of ten patients who were unselected except that none presented post-mortem evidence of primary liver disease; this group served as a control.

*Abstracts of the clinical records of these patients may be found in Reference 1.

The liver specimens, preserved in 4 per cent formaldehyde, from these three groups of patients were analyzed by the biochemist for total liver fat and total liver nitrogen. These specimens were identified to the biochemist by number only. Glycogen determinations were not done. The analyses for fat were performed, with minor modifications, by the chloroform extraction method used by Channon, Platt, and Smith.[2]

The effect of formalin fixation on liver lipids was investigated by Halliday,[3] who found that, although total solids and total cholesterol content were not significantly affected by treatment with formalin, the total fatty acid content decreased. The decrease was only slight during the first three months of formalin fixation but was considerable after longer periods, probably because of auto-oxidation. Weil,[4] working with nervous tissue, found that phosphatides were hydrolyzed after formalin treatment, but cholesterol and galactolipids were not appreciably changed. In view of these observations, lipoid partition determinations of our fixed specimens were considered inadvisable. We have found that specimens kept in formalin at room temperature show lower fat content than specimens from the same liver kept in the refrigerator, probably because of changes in the properties of certain phospholipids which either tend to diffuse into the formaldehyde or, upon treatment with formaldehyde, become less soluble in fat solvents such as chloroform. It must be emphasized that the analyses made on formalin-fixed liver tissues do not represent accurately the concentrations of fat in the fresh tissues but must be considered merely as reflections of the fresh tissue values. Each fat analysis was done in duplicate, and the differences between the duplicate determinations varied from 0 to 0.14 Gm. per 100 Gm. of tissue, averaging 0.09 Gm. per 100 Gm. of tissue.

RESULTS

The results of the analyses of the livers of the patients in Group I are presented in Table I. The average total fat content of these livers from patients with chronic alcoholism and cirrhosis who had received amino acids was 2.16 Gm. per 100 Gm. of tissue, and the average total liver protein (calculated from the total nitrogen) was 19.0 Gm. per 100 Gm. The liver weight averaged 1,607 Gm.

In Group II, consisting of patients who had had chronic alcoholism and cirrhosis of the liver but had not received amino acids, the total fat content of the liver specimens averaged 22.06 Gm. per 100 Gm. of tissue and the total protein content averaged 13.1 Gm. per 100 Gm. The range for total fat was

TABLE I

PATIENTS WITH CIRRHOSIS OF THE LIVER AND CHRONIC ALCOHOLISM TREATED WITH AMINO ACIDS*

PATIENT	LIVER WEIGHT (GM.)	TOTAL LIVER LIPIDS GM. PER 100 GM. OF TISSUE	TOTAL LIVER NITROGEN GM. PER 100 GM. OF TISSUE	TOTAL LIVER PROTEIN GM. PER 100 GM. OF TISSUE
J. R.	1,400	2.13	2.95	18.4
A. B.	2,360	1.89	3.09	19.3
E. C.	1,060	2.45	3.09	19.3
Average	1,607	2.16	3.04	19.0

*The liver weight was determined at the time of autopsy. The liver lipids and nitrogen were determined on formalin-fixed specimens. The total protein was derived from the total nitrogen determination.

from 2.23 to 35.60 Gm. per 100 Gm. and for total protein, from 3.2 to 19.0 Gm. per 100 Gm. The average liver weight was 2,738 Gm. The individual analyses are presented in Table II. [Ralli and her collaborators,[5,6] analyzing fresh liver specimens, found that the average total lipid content of livers from twenty-five patients with a history of chronic alcoholism (including eight patients with evidences of early or advanced cirrhosis) was 12.2 Gm. per 100 Gm. of tissue, with a range of from 2.0 to 34.8 Gm. per 100 Gm. The average liver weight of their group was 2,020 Gm. The eight patients in her group with cirrhosis of various stages and alcoholic histories had an average total liver lipid of 13.0 Gm. per 100 Gm. (with a range of 2.00 to 34.8 Gm. per 100 Gm.), and an average liver weight of 2,519 Gm.]

TABLE II

PATIENTS WITH CIRRHOSIS OF THE LIVER AND CHRONIC ALCOHOLISM WHO DID NOT RECEIVE AMINO ACIDS

TABLE III

PATIENTS WITHOUT PRIMARY DISEASE OF THE LIVER

PATIENT	DIAGNOSIS	LIVER WEIGHT (GM.)	TOTAL LIVER LIPIDS GM. PER 100 GM. OF TISSUE	TOTAL LIVER NITROGEN GM. PER 100 GM. OF TISSUE	TOTAL LIVER PROTEIN GM. PER 100 GM. OF TISSUE
E. I.	Hypertensive heart disease	2,500	4.33	2.52	15.7
F. A. P.	Prostatic hypertrophy and pyelitis	2,050	1.97		
A. G. D.	Hypertensive heart disease, pulmonary infarction	2,000	1.70		
F. B.	Aortic stenosis	1,700	3.68		
R. D.	Nephrosclerosis	2,000	3.11		
J. L. B.	Pulmonary tuberculosis	1,000	2.07	3.22	20.1
C. C.	Nephrosclerosis	2,100	3.19		
C. C.	Lung abscess	1,300	2.34		
W. V.	Carcinoma of colon	1,650	3.67		
T.	Myocardial infarction	2,250	4.03	3.34	20.8
Average		1,855	3.01	3.03	18.8

In Group III, consisting of patients dying of causes not related to primary disease of the liver, the total fat content of the liver specimens averaged 3.01 Gm. per 100 Gm., with a range of 1.70 to 4.33 Gm. per 100 Gm. The total protein (determined in only three instances) averaged 18.8 Gm. per 100 Gm. The liver weight averaged 1,855 Gm. [Ralli and co-workers[5] found that fresh livers from normal individuals who died of accidental injuries averaged a total lipid content of 4.98 Gm. per 100 Gm. of liver (with a range of 2.42 to 8.41 Gm.) and the liver weight averaged, 1,430 Gm.] The rather high average

liver weight of our patients in this group is due to the fact that in several patients chronic passive congestion of the liver secondary to circulatory insufficiency was present. The individual analyses are presented in Table III.

Examination of slides prepared from the livers analyzed revealed a rather close correlation between the extent of fatty infiltration evident microscopically and the amount of fat determined by analysis.

DISCUSSION

Admittedly, the number of cases is small and of little statistical significance. However, available data present very few studies of this character. Our comments here will concern themselves wholly with the type of cirrhosis described by Connor as "fatty cirrhosis."[7] The patients in Groups I and II are examples of this type of cirrhosis, as distinguished from toxic, biliary, syphilitic, and pigment cirrhosis.

From the data presented, two inferences are permissible:

(1) The percentage of liver protein in general varies inversely with the percentage of liver fat. Any discrepancies may be accounted for by changes in the glycogen content. It must be remembered that at least a part of the apparent increase in hepatic protein may be relative rather than actual, since the decrease in fat content would of itself result in an increased percentage of protein. The protective action of protein stores in the liver and body against hepatotoxic agents has been demonstrated in the experimental animal by Miller and Whipple,[8] and our analyses are suggestive confirmation of the same mechanism in man.

(2) The administration of the amino acid mixture to patients with cirrhosis of the liver and chronic alcoholism apparently resulted in a decrease in percentage of hepatic fat and a concomitant increase in percentage of hepatic protein. Of course, the ideal method of proof that the changes in liver fat and protein are a direct result of the action of the amino acids would be the determination of fat and protein content of liver biopsy specimens before and after the administration of amino acids; however, this procedure was not feasible in the patients we studied. The fact that all the patients in Groups I and II were chronically addicted to alcohol renders them a fairly homogeneous group and reduces the number of variable factors, as also does the determination of average values. It will be seen that, in Group II, the liver of only one patient (J. L.) exhibited fat and protein percentages and liver weight within the control range and within the range of specimens from patients treated with amino acids. Connor[7] states that in patients who have used alcohol excessively over a long period of time but have maintained a fairly good diet, fat may or may not be present and the liver is likely to be reduced in size.

The significance of fatty infiltration of the liver as a precursor of cirrhosis has been stressed recently.[7, 9] In experimental animals, fatty livers have been produced by high fat diets, cystine, starvation, cholesterol, and toxic agents such as alcohol, phlorizin, chloroform, carbon tetrachloride, phenylhydrazine, and phosphorus.[10, 11] In clinical medicine, fatty livers may develop in chronic alcoholism, diabetes, mellitus, pernicious anemia, poisonings with the chemicals mentioned above, yellow fever, eclampsia, acute yellow atrophy, marked obesity,

certain endocrine disorders, and lesions of the pituitary or midbrain. Fatty infiltration of the liver may lead to interference with tissue metabolism, with resultant degeneration of liver cells and replacement by perilobular fibrous tissue. It is readily seen that any agent which would decrease the rate of deposition of liver fat and accelerate its removal (i.e., a lipotropic agent[12]) might prevent the development of cirrhosis in fatty livers and would be of vast clinical significance. Recent theories of the pathogenesis of hepatic cirrhosis have been reviewed by Jolliffe and Jellinek,[13] and they express the belief that the investigations of Connor and his associates in the relationship between fatty liver and cirrhosis are among the most important advances.

The experimental background of lipotropic activity of raw pancreas, lecithin, choline, proteins, methionine, betaine, and constituents of vitamin B complex has recently been reviewed.[12] It has been shown that choline, methionine, and betaine are similar physiologically in their lipotropic activity and are similar chemically in that all possess labile methyl groups.[14] The lability of the methyl group and its potentiality for participating in transmethylation reactions may be the determining factor in the lipotropic activity of these substances and may be important in detoxification processes in the body. Lowry and co-workers[15] reported that the administration of choline or a high casein diet to rats with experimental dietary cirrhosis resulted in regeneration of liver cells, disappearance of degenerative fatty changes, and decrease in liver size. Daft, Sebrell, and Lillie[16] demonstrated that cirrhosis of the liver could be *prevented* by the administration of methionine or choline or casein, singly or in combination, to rats receiving low protein rations and alcohol. The methionine content of casein is 3 per cent,[17] and it has been shown that methionine may supply methyl groups, for the formation of choline or an active compound derived from choline,[18] and that the administration of methionine accelerates the rate of phospholipid turnover in the liver.[19] Recognizing that results in experimental animals are not directly applicable to the interpretation of metabolic changes in human beings, we believe, nevertheless, that the lipotropic activity of the amino acids administered in our study probably was due to the methionine content of the amino acid mixture, which was prepared by hydrolyzing casein, and contains amino acids in the same proportion as they are found in casein. The lipotropic activity of choline has been demonstrated conclusively,[11, 12, 15, 20] and the good results reported by Broun and Muether,[21] in treating patients with hepatic cirrhosis with choline and a low fat diet, may, in part, be due to the lipotropism of choline.

Good results have been reported in treating cirrhosis of the liver with a high carbohydrate, high protein, low fat diet, with vitamin supplements,[22, 23] and it remains to be seen whether the prognosis can be influenced *still* more favorably by the additional use of choline, methionine, or amino acid mixtures.

SUMMARY

1. Liver specimens (preserved in formalin) from patients with cirrhosis of the liver and chronic alcoholism were analyzed for their total lipid and total nitrogen content. It was found that specimens from patients who had received amino acids as part of their therapy contained a greater percentage of protein

and a lesser percentage of fat than specimens from patients who had not received amino acids.

2. It is postulated that these results indicate a lipotropic activity of the amino acid mixture, probably due primarily to their methionine content.

3. The percentages of liver fat and of liver protein were found to vary inversely.

4. The clinical significance of these findings is briefly discussed.

LABORATORY METHODS

GENERAL

A SIMPLE METHOD FOR THE SEPARATION OF BLOOD SERUM*

Lea C. Steeves, B.A., M.D., Montreal, Can.

THE following method has been found to be simple and timesaving in the preparation of arsphenaminized serum for intraspinal therapy. The principle is adapted from commercial plasma separation and transfusion sets and can be used for several types of cell serum or cell plasma separation.

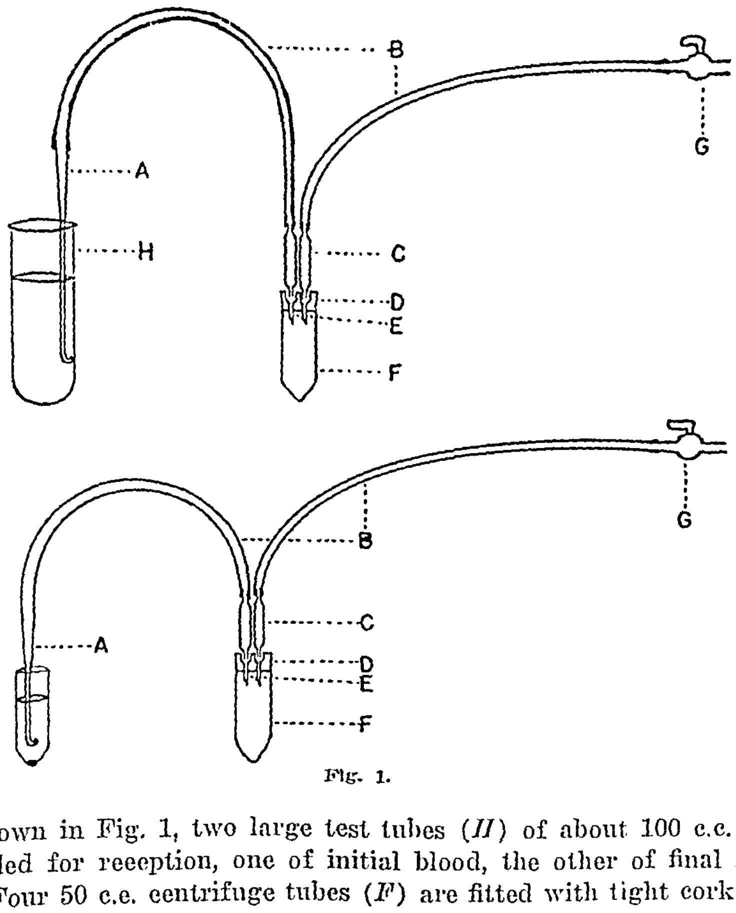

Fig. 1.

As shown in Fig. 1, two large test tubes (*H*) of about 100 c.c. capacity are provided for reception, one of initial blood, the other of final serum or plasma. Four 50 c.c. centrifuge tubes (*F*) are fitted with tight cork stoppers

*From the Department of Neurology and Neurosurgery, McGill University, and the Montreal Neurological Institute, Montreal.

Received for publication, July 2, 1942.

Miss Doris Brophy suggested the pipettes and prepared Fig. 1.

(*D*),* through each of which two 18-gauge blood needles (*E*) are inserted. The hubs of the needles are countersunk in the cork, and one-half an inch is cut off the top of the centrifuge tube in order that the assembly may spin freely in the ordinary laboratory centrifuge. A glass adaptor (*C*), as commonly used in intravenous sets, is provided for each needle, and to each adaptor a short length of rubber tubing (*B*) is attached. A glass pipette (*A*) with approximately 18-gauge bore at the U tip is provided for each centrifuge tube. Laboratory vacuum taps (*G*) provide the necessary suction.

The entire apparatus can be neatly packed for sterilizing, wrapped under one cover, in the following units: (1) initial and final reception tubes; (2) centrifuge tubes with corks and needles inserted; (3) adaptors, tubing, and pipettes; (4) adaptors and tubing for connection to unsterile vacuum tap.

Assembly can be carried out by one ungloved operator without contamination. Serum or plasma can be separated with very little waste because of the U pipette which reduces upward currents from the cell fluid interface. By removing the adaptors, unit two can be centrifuged uncontaminated to remove residual blood cells. This procedure can be repeated as desired with loss of only a very few cubic centimeters of fluid upon each pipetting. In the case of arsphenaminized serum, Fordyce, as quoted by Moore,[1] centrifuges twice.

SUMMARY

A simple, semiclosed apparatus for rapid separation of cell serum or cell plasma preparations is described. It can be readily assembled from laboratory materials and can be used by one person unaided without danger of contamination.

A QUADRUPLE STAINING METHOD FOR TISSUES†

S. S. KALTER, LAWRENCE, KAN.

RECENT advances in staining procedures show a definite trend toward the employment of various differential staining methods for the study of normal as well as pathologic tissues. The evolution of staining techniques need not be discussed here, as the interested student need only to turn to a monograph by Conn[1] for further information.

The foundation for this quadruple stain was Flemming's triple stain (1891), which appears to be the basis for various other multiple staining methods. It seems, however, for obvious reasons, that histologists and pathologists, in the

*Tapered rubber stoppers give a more air-tight fit but must be renewed after fifteen to twenty autoclavings.

†From the Department of Bacteriology, University of Kansas.
Received for publication, July 7, 1942.

main, restrict their tissue staining to hematoxylin-eosin, with Mallory's[2] connective tissue stain being employed when a tinctorial differentiation was wanted. The botanists, on the other hand, basing their procedures on Flemming's stain, as did Conant[3] and Johansen,[4] investigated the applicability of more complex procedures for the study of mitosis as well as differentiation of botanical tissues.

Dratman,[5] following Conant's work, proceeded to introduce this technique for the study of animal tissue. The work herein described is, therefore, a continuation of the work of Dratman. This technique is essentially that of Dratman, with modifications made to insure more constant results and to bring out sharper differentiation of the cellular elements.

METHOD

Tissues are fixed and dehydrated by any preferred method. We have given preference to Bouin's fixative, as it was demonstrated by Baird,[6] to produce a minimum amount of shrinkage and distortion in the cellular elements, with uniform results and delicacy of fixation. In using Bouin's solution, the picric acid must be removed by using a few drops of lithium carbonate in the 70 per cent alcohol dehydration series. In the use of Zenker's fixative the mercuric chloride must be removed.

The tissues, after being embedded in paraffin, give the best staining results when sectioned at 7.5 micra. In affixing the tissues to slides, the loss of tissues is negligible if the slides are thoroughly dried in an incubator at 37° C. overnight. The use of albumin water causes a cloudiness to appear in the staining reaction.

Of utmost importance is the preparation of the dyes. The dye solutions prepared as follows, have been found to give the best results:

1. Safranin O:* 0.2 Gm. of safranin O in 100 c.c. of 50 per cent ethyl alcohol plus 4 c.c. of formalin to act as a mordant and 0.5 Gm. of sodium acetate to accentuate the color.

2. Gentian violet (crystal violet):† 0.5 Gm. in 100 c.c. water.

3. Fast green FCF:‡ A saturated clove oil solution is made using 0.5 Gm. of the dye in 80 c.c. of the oil. The dye is left in the clove oil twenty-four hours with occasional shaking, then filtered through cotton. To 40 c.c. of this solution is added 30 c.c. of orange II.

4. Orange II:§ Saturate clove oil with 0.5 Gm. of the dye and allow to stand twenty-four hours with occasional shaking and filter through cotton.

The staining procedure is as follows: (1) Slides run down to tap water; (2) stained in safranin O, 24 hours; (3) tap water wash; (4) gentian violet, 1 to 2 minutes; (5) tap water wash; (6) 50 per cent ethyl alcohol, 2 minutes; (7) 95 per cent ethyl alcohol, 2 minutes; (8) fast green-orange II—differentiate under the microscope after 5 minutes; (9) pure clove oil for 10 minutes; (10) pure orange II—differentiate under the microscope after 15 minutes; (11) xylol (two changes), 10 minutes each.

*Henry Heil Chemical Co., US-8; National Aniline and Chemical Co., Certification No. NS-8.

†Gruber 9.37; National Aniline and Chemical Co., Certification No. NC-18.

‡National Aniline and Chemical Co., Certification No. NGF-4.

§Coleman and Bell Co.

In steps 8 and 10 the time expressed is a minimum due to various factors such as thickness of the tissues and cellular activity. The tissues are differentiated under the microscope in step 8 and are removed as soon as the connective tissue is green. Further differentiation takes place in the pure clove oil as well as in the orange II; therefore, clearing in the pure clove oil for ten minutes is essential.

RESULTS

Nuclei stain red, with the nucleoli staining purple or a bright purple-red, while the nuclear membrane stains a dark red. The cellular cytoplasm stains from pink to red, with a marked exception being noted in the medulla of the kidney. Here the cytoplasm of the cells making up the descending and ascending limbs of Henle's loop stain light green. The connective tissue stains green, while large elastic fibers or areas where elastic tissue predominates are sharply differentiated in yellow. The fibroblasts are green with purple nuclei. Muscular tissue usually stains a light tan, with the striations as dark bands. Red blood cells are orange. The polymorphonuclears have purple nuclei.

DISCUSSION

This method, although it is a differential connective tissue stain, cannot be compared with Mallory's. The time element as well as the striking connective tissue differentiation obtained by Mallory's stain makes it one of the most outstanding differential techniques now employed.

On the other hand, the main feature obtained by this quadruple stain is the benefits obtained by students of histology. Because of the lightness of the colors, the various elements of the tissues are not masked. The tissues can then be studied from the structural aspects as well as by the differential staining.

SURFACE GROWTH OF CLOSTRIDIUM WELCHII

EDWARD STEINFIELD, M.D., AND MARGARET WATSON, PHILADELPHIA, PA.

DUE to the recent investigations of Kligler and Guggenheim,[1] it has been demonstrated that the determining factor in anaerobiosis is the reduction potential of the medium rather than other factors. In their experiments they found that growth of *Clostridium welchii* occurred in tubes with over 95 per cent of normal oxygen tension, provided an adequate amount of ascorbic acid was present. The reduction potential at which growth occurred was about −0.125 volt. These observations supplemented earlier reports of Lepper and Martin[2] who found by potentiometer and indicator methods that the Eh of freshly prepared cooked meat mediums was of the order of −0.174 volt to −0.2 volt, 1 or 2 cm. from the surface. Since cooked meat medium with a petrolatum seal is uniformly satisfactory in the cultivation of *Cl. welchii* and similar anaerobes, it is obvious that the reduction potential can be taken as a measure of the availability of an anaerobic method regardless of the hypothetical explanation of its mechanism. We have had occasion to verify the statements of Lepper and Martin and have obtained similar readings of the Eh of sealed cooked meat medium tubes by indicator methods.

The practical implication of the work of Kligler and Guggenheim is in the possibility of surface growth of *Cl. welchii* and similar anaerobes which are important, particularly in gas gangrene. Among the various methods which make this possible are the Spray anaerobic dish and the Brewer anaerobic jar. The latter is particularly valuable in the cultivation of obligate anaerobes. The possibility of using stock equipment and material has led us to improvise upon the observations of Kligler and Guggenheim with the use of the ordinary Petri dish.

The method is as follows:

Test tubes containing 12 to 15 c.c. of plain agar are heated to melting point and allowed to cool slowly as in the usual preparation for blood agar plates. Sterile defibrinated blood* is added and immediately thereafter 50 mg. of the sodium salt of ascorbic acid. The latter can be obtained commercially in the form of one cubic centimeter ampules, each containing 100 mg. of sodium ascorbate in solution. These may be diluted with equal volumes of normal saline solution and the appropriate amount added to the blood agar tube. The treated blood agar is poured into sterile Petri dishes and allowed to solidify. Within one-half to one hour the plate darkens due to the reduction of hemoglobin. Circular seals of cellophane slightly smaller than the inner compartment of the Petri dish are cut out, immersed in 70 per cent alcohol for several minutes, and

Received for publication, July 7, 1942.

*Horse blood is preferable in demonstrating clear-cut beta hemolysis by *Cl. welchii*, but sheep or human blood may be used for convenience.

dried between layers of sterile filter paper. They may be kept in several such layers within sterile Petri dishes. Autoclave sterilization is less desirable since it tends to wrinkle the cellophane. We have found the product commercially labeled "No. 300 moisture proof" quite satisfactory. After streaking cultures or material presumably containing *Cl. welchii* over the surface of the treated blood agar, a cellophane seal handled with a flamed forceps is gently placed over the agar surface and rolled smoothly against it with a bit of sterile glass tubing threaded upon a wire. By this means the oxygen tension is kept to a minimum; the plate can be examined by transmitted light and handled in any position. Subcultures can easily be made by lifting the edge of the cellophane cover with forceps without undue distortion of the surface. Hemolysis can be judged, though not quite so sharply as in the usual blood agar plate because of the reduced hemoglobin. It is quite possible to obtain somewhat similar results with stored blood agar plates by applying the same amounts of sodium ascorbate to the surface of the plate and carrying the material along with the platinum loop or sterile swab during streaking. In such preparations it is possible to note the areas where the reducing action is lacking with consequent absence of growth. The method in general has so far been applied to strains growing under laboratory conditions. However, since these cultures fail to grow by ordinary aerobic methods, it can be assumed that their anaerobic properties are still maintained. In order to verify the sealing effect of the cellophane, agar plates containing the sodium ascorbate and an indicator such as 2, 6-dibromophenolindophenol were set up and kept at room temperature. All plates showed decolorization of the dye, but controls without cellophane gradually exhibited oxidation from the surface downward; those with cellophane remained decolorized for from seven to ten days. Although this indicator does not register the optimum Eh which can be obtained, it is useful in this particular observation because of its clearcut readings.

There are certain disadvantages to the method. So far it has been found difficult to apply to the sugar mediums and for the culture of *Cl. tetani.* A moisture film may make single colony isolation difficult. The expenditure for the sodium ascorbate would have to be considered in large scale observations. It may be advisable to adapt this method, if possible, to the use of such reducing mediums as cysteine hydrochloride or sodium thioglycollate. These have recently been reviewed and amplified by Brewer.[3] Spray[4] has also mentioned the use of flat sheets of cellulose over deep agar plates. Although these approaches to surface culture are no doubt being investigated, we feel that this brief description may induce trial and improvement of such methods. A similar technique may prove useful in some exigencies of time and material or where the use of hydrogen jars is undesirable.

ADAPTATION OF A KAHN SHAKER FOR HOMOGENIZING SPECIMENS FOR BACTERIOLOGIC PROCEDURES

Lillian Buxbaum,* M.S., New York, N. Y.

In the course of our laboratory work it is often necessary to shake vigorously several different types of bacterial samples to obtain homogenous suspensions. To expedite and simplify this procedure, a mechanical shaker is considered desirable. A Kahn shaker that was already part of our laboratory equipment was satisfactorily adapted for our needs. The idea for adapting a Kahn shaker was obtained from a bottle shaker manufactured by the Precision Scientific Company of Chicago (catalogue No. 5892).

Fig. 1.

Lead-coated copper, which is rust-resistant, 1 mm. in thickness, was used to make a tray 14 inches long, 12 inches wide, and 2 inches deep (Fig. 1). Specifications of the tray were limited by the apparatus already in the shaker which is used for shaking hemocytometers. Both the tray and the latter apparatus are fitted into the ledge of the shaker. The tray is removable so that it can be easily cleaned and sterilized.

Metal holders (Fig. 2) were ordered from the Standard Scientific Supply Company of New York. Spring brass was the metal of choice for these holders because of its malleability and tensile strength. Two 1 mm. metal bands, 1 inch wide and 6 inches long, are placed at right angles and soldered together. The bands are bent at a 90-degree angle so that the four upright arms are 2 inches in height. The four ends are curved in order to hold the specimen containers

Received for publication, July 14, 1942.

*Assistant Bacteriologist, Pathological Laboratory, Willard Parker Hospital.

securely. The width at the base of the finished holder is 2 inches. The top can be expanded to 4 inches or contracted to 2 inches, depending on the size of the container used. Rivets are used to attach the holders to the tray at a distance of three and one-half inches from the center of each holder.

The shaking apparatus, thus modified, was utilized at first to homogenize sputum for concentration of *Mycobacterium tuberculosis.* Half pint wax cups with a 2-inch base diameter, a 3-inch brim diameter, and 3½ inches in height were used as containers for these specimens. All tenacious masses were completely broken up, and good digestion of the sputum was obtained after adding 3 per cent sodium hydroxide and shaking for twenty minutes.

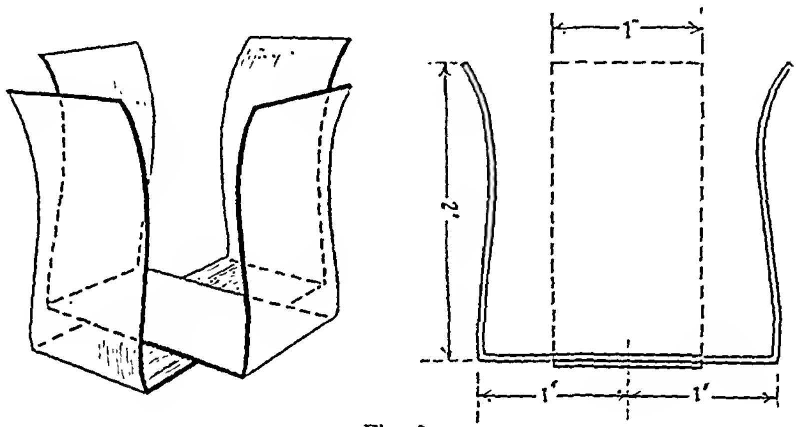

Fig. 2.

Due to the fact that the holders can be adjusted, different sizes and types of containers can be inserted and held securely by the flexible metal strips. Among other uses, it was found that homogenous suspensions of streptococcus growth in some liquid media resulted after shaking for from four to six minutes. As this organism produces a granular growth in broth, the shaker proved invaluable when used in preparing different amounts of antigens for the Griffiths' typing of hemolytic streptococci.

The hospital tinsmith, Frank J. Musacchia, Jr., constructed the tray and riveted the holders.

I wish to thank Dr. Vera B. Dolgopol for her suggestions which aided in the preparation of this paper.

ROLLER RIM-DRIVE KYMOGRAPHS

R. P. WALTON, M.D., F. M. COOK, B.S., AND A. B. CULLEN, M.S.,
CHARLESTON, S. C., AND UNIVERSITY, MISS.*

KYMOGRAPHS have always represented one of the major equipment problems of pharmacology and physiology laboratories. The chief difficulty in their construction is occasioned by the need for wide ranges of speed, and, at present, these are obtained almost exclusively by shifting gears or rearranging belts, with usually a rheostat or governor control of the motor. These motor controls are limited to a 6-to-1 range usually, or as a maximum, a 10-to-1 range. Additionally, the rheostat control even at the 6-to-1 range involves serious loss of torque at the lower speeds, since its effect is essentially to dissipate power. This, similarly, is a disadvantage of fan-controlled spring motors.

A distinct improvement will be the development of some device which will give smooth, continuous control of small motors over a speed range of about 100 to 1. By the use of reducing gears, two such speed areas could be made available with only one shift of gears (or change of drives). Speed ranges of 10,000 to 1 would then be available, and this covers practically all the needs of pharmacologic and physiologic work. A wide range of control is now commercially available with large motors. For instance, the Crocker-Wheeler polyspeed motors operate with a variable speed 3 phase A. C. motor which has separately excited rotor and stator coils and has essentially the same characteristics as a D. C. shunt motor; that is, constant torque at different speeds.[1] Another possible type of motor control is that described by Ryder in which a D. C. motor is shunt wound and has a separately excited armature and field.[2] The armature voltage might be varied from zero to maximum by means of a grid-controlled rectifier acting as a variable voltage source, a function which can be satisfactorily performed by a thyratron tube. There are other arrangements of a purely mechanical nature by which the desired motor control might be obtained. One is by the use of small hydraulic, piston-drive motors and pumps (in which variations of fluid flow are subject to valve control). Another is by the use of a planetary drive system in which the differential rate of two motors might be subject to a wider range of control than is the case with a single motor.

We have made tentative experiments with each of these possible arrangements and in each case have found enough complications and disadvantages to preclude the immediate prospect of using them as kymograph drives which could be developed as a practical improvement over existing methods. These possibilities are mentioned, however, since with subsequent technical developments or in other hands they might be satisfactorily adapted to this particular purpose.

The arrangement which we have developed and put into use involves a simple mechanical principle which without any new meshing of gears gives the needed wide range of speeds and is capable of construction at a relatively low

*From the Departments of Pharmacology, Medical College of the State of South Carolina and School of Medicine, University of Mississippi.
Received for publication, July 17, 1942.

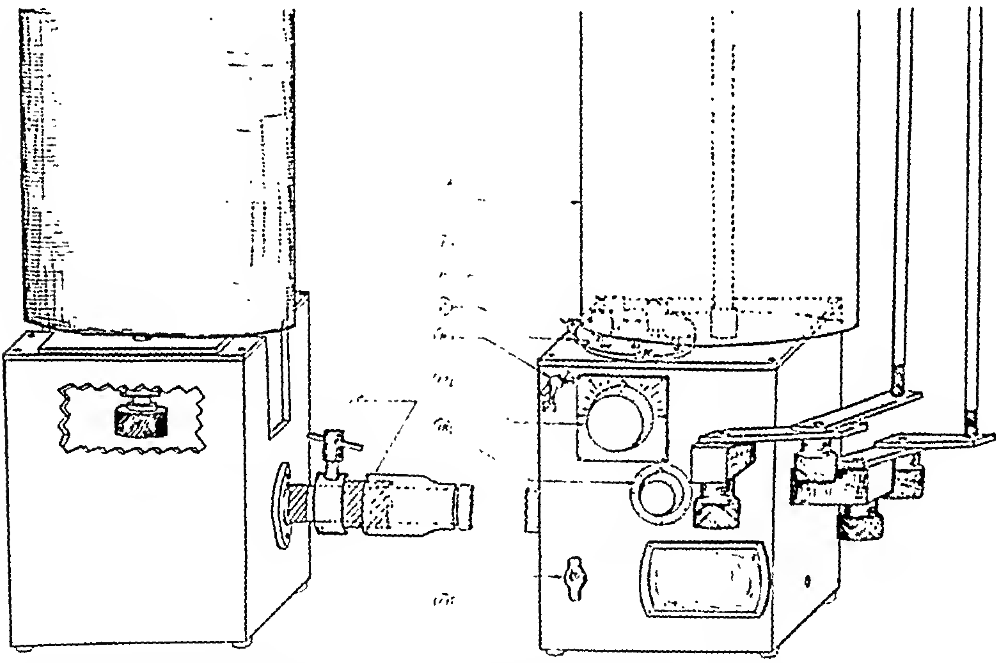
cost under ordinary shop conditions. Its chief point of novelty lies in the use of the roller rim-drive principle such as has been used in musical record players for the last several years. This is essentially a small, power-driven roller operating by friction against the inner shell of a kymograph drum. Commercial friction drives at a more central point of power have not been satisfactory in our experience, but this type of friction drive at the most peripheral point of the system has proved exceptionally satisfactory. One such drive has been used now for five years in these laboratories and has always given smooth operation without slipping. Our presently preferred kymograph design operates at top speed with a pull of ten pounds at the periphery of an eight-inch drum, and, under test conditions up to this maximum pull, there has been no slipping. This is an extreme test, since some widely used commercial kymographs are stopped by less than one-pound pull at the drum periphery.

The unique advantage of the roller rim-drive lies in the fact that several rollers can be power driven within the shell of the drum, and, by a fairly simple arrangement, any single roller can be selected for driving contact while the other rollers are allowed to idle. Thus different ranges of speed can be made immediately available without the usual changing of gears or shifting of drive belts. The fact that there is actually no new meshing of gears in any of these changes of speeds eliminates the need for the more precise type of machining construction which is necessary when several gear shifts are required.

This principle can be illustrated best by the simplest theoretical arrangement in which only two rollers are being driven inside the drum shell. These are being driven at different rates of speed by a motor and gear box in a housing below the drum. The rollers are mounted on free, movable arms of bar iron and connected by small spur gears to the power shafts. The arms rotate freely about cylinders which enclose the fixed power shafts. By two simple maneuvers, one roller can be released from contact with the inside shell of the drum and the other brought into contact. This contact can be maintained with a tension spring. With rheostat control of the motor, which usually gives satisfactory control over a range of 6 to 1, two areas of speed range are made available. This represents the simplest arrangement of multiple drives, and the construction details are simple. By increasing the number of power-driven shafts and their attached rotating arms and roller drives, additional speed ranges are made available and without the necessity of meshing new gear combinations. The mechanical difficulties of arranging side arms underneath the drum, however, increase with the number of side arms and a point may be reached where there may be interference with recording instruments.

We have found that the most suitable means of making available several such speed areas is a system which drives a number of contact rollers from one circular gear box, which itself can be freely rotated about a central power shaft coming directly from the motor. The whole gear housing can be shifted away from the drum periphery enough to release the friction contact of any of its rollers, the gear system rotated to place the selected roller drive in position for contact with the rim, and the gear housing shifted back to establish contact of the selected roller with the rim.

This gear box mechanism is of a clock-work type, and we have preferred a gear reduction of about 6 to 1 between each roller drive shaft. With five such roller drives and ordinary rheostat control, a continuous selection of speeds is available over a range of about 7,500 to 1. This permits a top speed which completely revolves a ten-foot paper in about one minute and a lowest speed which revolves the paper once in about five days. Stated differently, the paper can be driven at about 5.0 cm. per second at top speed and at about 2.4 cm. per hour at the lowest speed. Any speed within this range can be selected immediately and put in operation without disturbing the continuity of the tracing. There is no disturbing jar of the kymograph with speed changes, there is no waiting interval for a train of gears to catch up, and there is no forward jerk of the drum as new gears are meshed. These speed changes are obtained by knob controls placed out of the area of the support rods and recording instruments.



Figs. 1, 4, and 5.—*1*, Drive roller; *2*, indicator plate; *3*, gear housing; *4*, bevel gears; *5*, support for shaft to bevel gear; *6*, coupling; *7*, flexible shafting; *8*, motor mounting; *9*, drum shaft; *10*, stabilizing post; *11*, cam acting on gear housing to disengage roller; *12*, spring acting in gear housing to maintain friction of roller; *13*, rheostat; *14*, motor; *15*, drum; *16*, knob to cam shaft; *17*, knob to bevel gear; *18*, knob to rheostat; *19*, on-off power switch; *20*, spreader arrangement.

Fig. 1.—Schematic view of entire kymograph.

The details of this construction are given below. Additionally some features of kymograph assembly are mentioned which may be helpful to those particularly interested in cutting down costs. A rugged kymograph giving the above speed range and operating with adjustable large double drums can be assembled from less than $35 worth of parts in a shop equipped with a lathe and ordinary metal working equipment.

Drums.—The drums are made of laminated bakelite tubing (Synthane) which can be obtained in varying diameters and can be cut to order in various lengths. We have used such drums for five years and consider them preferable to metal drums. Heads are machined from a plastic slab or, adequately enough,

from plywood with a top covering of smooth asbestos composition board.* The lower head is fixed in the drum about one to two inches from the lower edge. This allows room for the rubber rollers to project up inside the shell of the drum. The drum itself with a central shaft of metal tubing idles on a shaft of three-fourth-inch diameter rodding attached to the base.

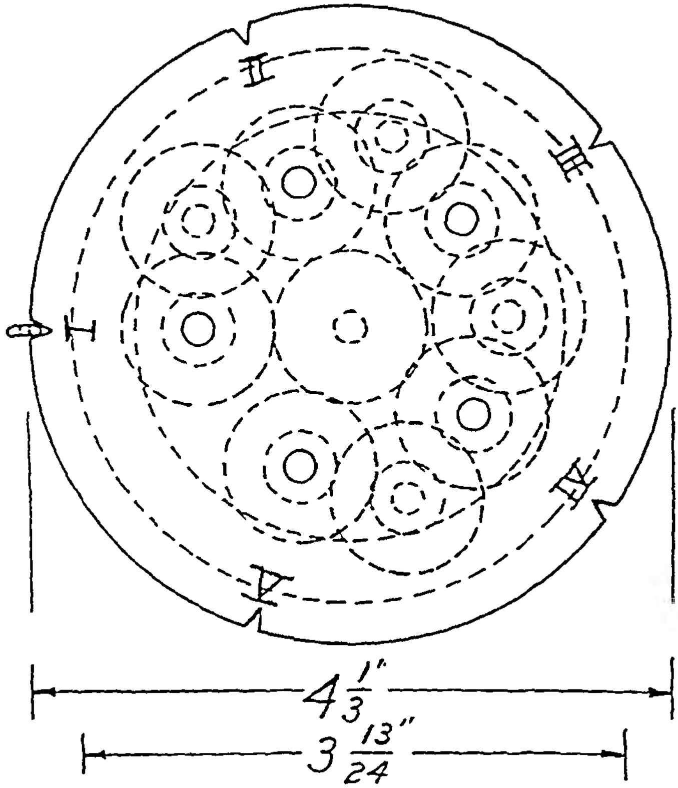


Fig. 2.—Top view of gear mechanism.

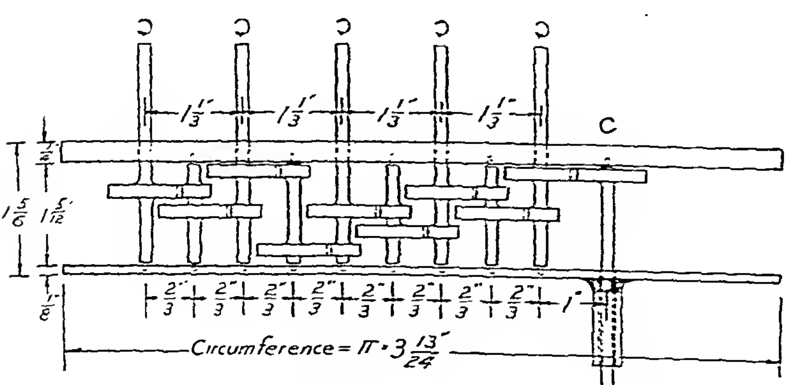

Fig. 3.—Gear mechanism diagrammatically shown in lateral plane.

Base.—The iron base is cast to order as a rectangular box weighing about thirty-five pounds. The bottom is left open and has rubber bumpers screwed up into the rim. The top is covered with a rolled steel plate.

*Decorative Flexboard, Johns-Manville Corp.

Idler Drum and Base.—The idler drum and base are the same as the motor-driven unit, except that the shaft of three-fourth-inch rodding is mounted on a movable plate, which can be slipped back and forth on the base. A heavy, knurled knob connects with this movable plate through a center groove in the top of the base. The drum bases are separated from each other by telescoping pieces of pipe with a threaded attachment for precision adjustments.

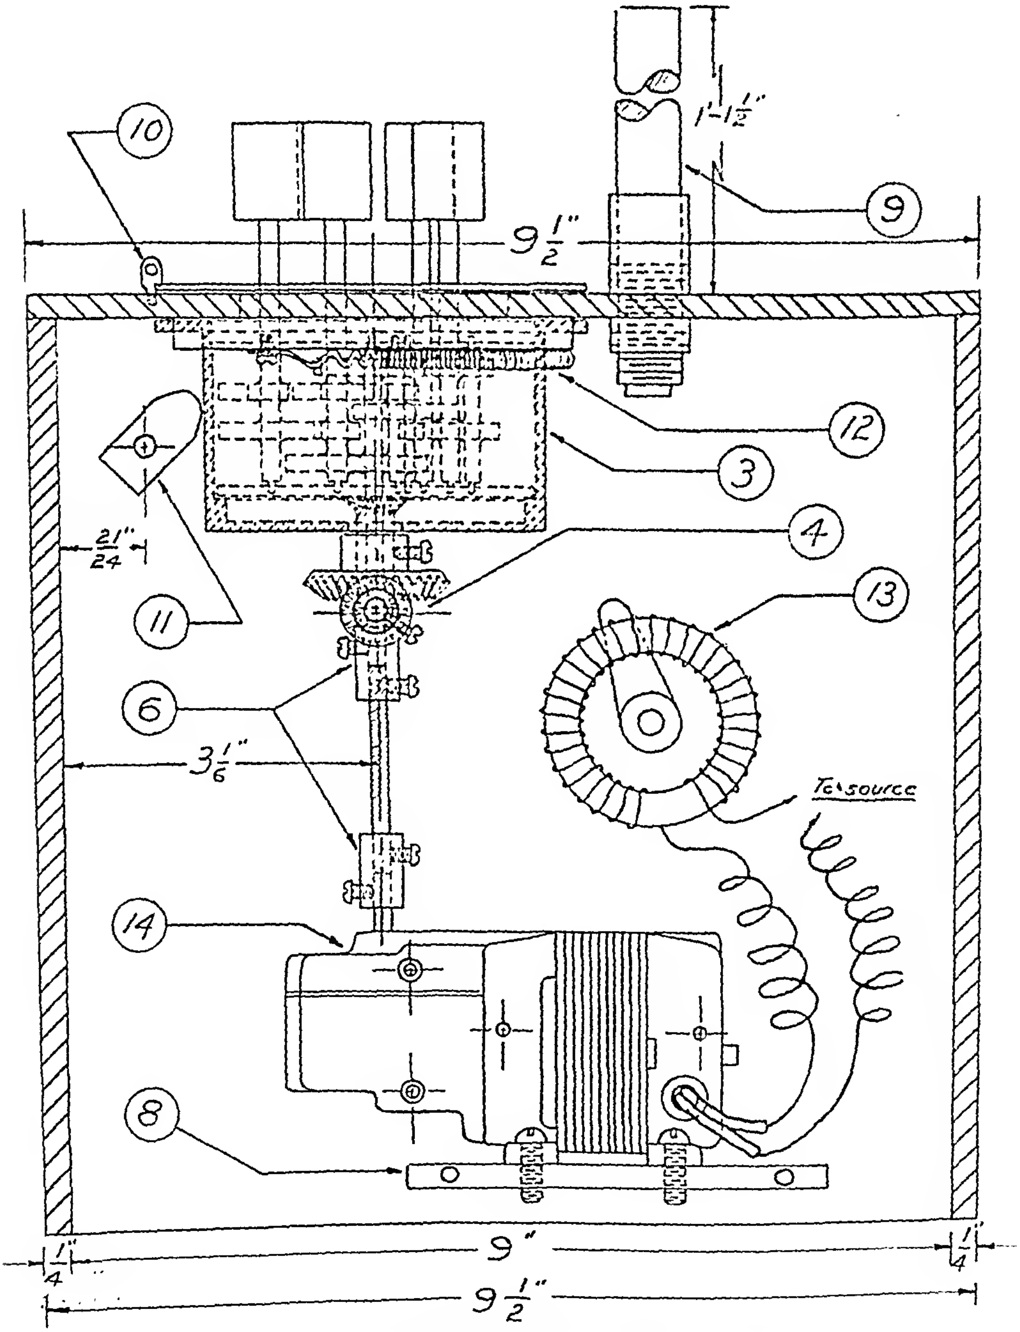

Fig. 4.—Front view (exposed) of gear mechanism.

Gear Box.—The clockwork mechanism is mounted inside a piece of four-inch pipe, and this housing is flanged at the top so as to slide in grooved backets attached to the top plate. A spring maintains tension of the entire housing toward the periphery of the drum. This gear housing is moved back away from the drum periphery by means of a cam shaft operated by a knob in the front of the base. The mechanism is made up of gears with twelve and thirty teeth each. Since each roller drive shaft must be turning in the same direction, two pairs of

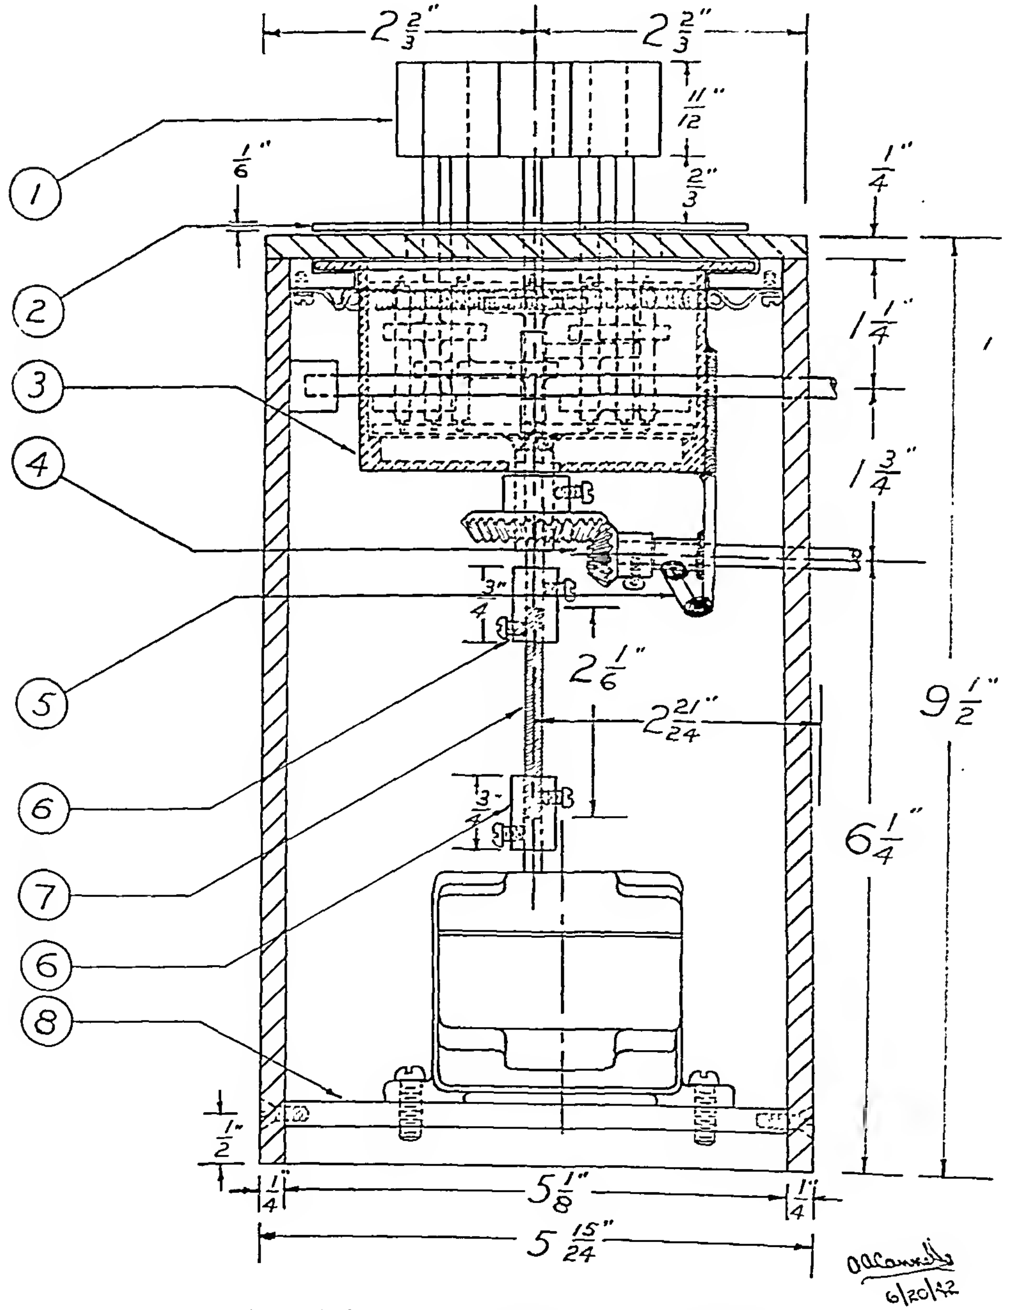

Fig. 5.—Left side view (exposed) of gear mechanism.

such gears are necessary, which, with the gear ratios of 12 and 30, make a speed reduction of 6.25 from one drive shaft to the next. The main drive shaft from the motor enters at the center of the gear housing and drives at a rate of 40 or 80 r.p.m. This low speed subjects the gear mechanism to very little wear and obviates the need for an oil bath or special oiling arrangements. This motor drive shaft is made up partly of a section of flexible shafting since the motor is stationary while the gear box is moved back and forth about one-fourth inch. The gears are mounted on a circular plate which turns smoothly on an offset within the housing and is connected by a threaded and soldered metal tube with a bevel gear placed around the central gear shaft below the gear housing. This bevel gear is turned by a smaller bevel gear which is on a shaft operated by a knob from the front of the base. This bevel gear arrangement is not entirely necessary since there is actually very little interference or inconvenience if the gear platform is simply turned by hand, the rollers and their shafts above the base plate being easily accessible. The correct spacing of the gear centers is necessary in order to minimize "back-lash," which can produce an irregular rate with an unloaded fast drum. The measurements shown in the diagram are approximate and, in setting up the gears, must be calculated more accurately from the known pitch diameter of the gears.

The drive rollers are made of ordinary rubber pressure tubing spiked on to each of the five drive shafts. Considerable variation in size of rollers is possible, which correspondingly varies the drum speeds.

LIST OF MATERIALS AND MANUFACTURERS (EFFECTIVE BEFORE PRESENT EMERGENCY)

Drums. Natural Synthane xx free-machining tubing. 8 inch inside diameter by $\frac{1}{16}$ inch wall. Two 12 inch lengths.
Synthane Corp., Oaks, Pa.

Motor with worm drive reduction.
Speedway Mfg. Co., 1834 South 52nd Ave., Cicero, Ill.

Brass gears. Spur gears. 10 with 12 teeth (No. G163)
10 with 30 teeth (No. G174)
Bevel gears. 1 pair with 18 and 36 teeth (No. G485)
Cat. No. 52. Boston Gear Works, N. Quincy, Mass.

Bases. Two iron castings of 33 lb. at .07
Memphis Machine Works, Memphis, Tenn.

Power rheostat. 75 watt, 300 ohm. No. 27-457
Flexible shafting No. 73-290
On-off switch No. 34-520
Bar knob No. 55076
Fluted knobs No. 55087

Switch plates, dial plates, power cord, crystallizing lacquer, etc.
Cat. No. 107. Allied Radio, 833 W. Jackson Blvd., Chicago, Ill.

Cold rolled steel shafting, mild steel rolled plates, bar iron, spreader pipes, etc.
Lewis Supply Co., Memphis, Tenn.

INTRAVENOUS ADMINISTRATION OF OXYGEN

F. S. Grodins, M.S., M.D., A. C. Ivy, M.D., Ph.D., and H. F. Adler, Ph.D.
Chicago, Ill.

A RECENT report[1] claims markedly beneficial effects from the intravenous administration of relatively minute amounts of oxygen. It was stated that therapeutic results were obtained with as little as from 0.2 to 0.3 c.c. per kilogram per minute and that this method of administration was more effective than oxygen by any other route. It seemed rather difficult to account for these results, since the amount of oxygen administered is less than 10 per cent (1 to 7 per cent) of the average basal requirement. Moreover, it has previously been reported[2, 3] that intravenous oxygen in larger amounts not only is unable to correct an existing anoxemia but may actually produce an anoxemia when none is present. In view of these facts, the problem has been reinvestigated.

METHODS

Dogs anesthetized with pentobarbital were used in all experiments. Oxygen for intravenous administration was obtained from an ordinary Linde tank fitted with a reducing valve to control the delivery pressure and a needle valve to control the flow. The gas was led through an orifice meter calibrated to measure the rate of flow in cubic centimeters per minute and was administered to the animal through two 27-gauge needles, one in each brachial vein. When oxygen was given by trachea, a closed system with suitable valves to prevent rebreathing was employed. Carotid blood pressure and respiratory movements were recorded on a smoked drum. Blood arterial oxygen was determined by the manometric method of Van Slyke.[4]

RESULTS

Effect on Respiration.—Twelve animals were studied (Table I). In ten animals with intact vagi, intravenous oxygen in amounts as small as 0.21 to 0.64 c.c. per kilogram per minute caused changes in respiration. The rate was most consistently affected, being increased in all cases. The effect on depth was more variable, increases, decreases, or no change occurring with approximately equal frequency. However, the most typical response, at least initially, appeared to be rapid, shallow breathing (Fig. 1). In larger amounts, the respiratory effects were more marked. In three vagotomized dogs, intravenous oxygen produced primarily an increase in depth, the increase in rate being less conspicuous (Fig. 2).

Effect on Blood Pressure.—The blood pressure was affected less consistently than the respiration. In general, small amounts of oxygen produced little

From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.
Received for publication, July 29, 1942.

change, whereas larger amounts lowered the pressure. However, there was marked individual variation.

Cardiac Froth.—Small amounts of oxygen (0.20 to 0.35 c.c. per kilogram per minute) did not produce audible cardiac froth. Larger amounts (1.0 to 2.5 c.c. per kilogram per minute) produced audible froth in all cases. This dis-

appeared quite rapidly (five to ten minutes) after the intravenous oxygen was stopped.

Arterial Oxygen Content.—Blood arterial oxygen was followed in six animals. In five of the six cases, intravenous oxygen in amounts varying from 0.35 to 2.3 c.c. per kilogram per minute decreased the arterial oxygen in amounts varying from 6.5 to 35 per cent.

Fatal Dose.—Dog 7 was killed by 3.2 c.c. per kilogram per minute intravenously.

DISCUSSION

In general, our results are in agreement with those of earlier investigators[2, 3] in so far as changes in respiration, blood pressure, and arterial oxygen are concerned. However, we found these changes to occur with smaller amounts of oxygen than were employed by these workers. From a physiologic viewpoint, several questions arise.

1. *Mechanism of Respiratory Changes.*—The most typical respiratory response to intravenous oxygen was a rapid shallow breathing (Fig. 1). This is the type of response reported by Binger, Brow, and Branch,[5] who produced multiple pulmonary emboli by the intravenous injection of starch granules in dogs, and by Dunn,[6] who performed a similar experiment in the goat. In the latter's experiments, no anoxemia was observed. In Binger's experiments, anoxemia

was produced. However, correction of the anoxemia by the inhalation of 90 per cent oxygen did not change the respiratory response. Freezing of the vagi, however, changed the response to a slow, deep respiration. These authors attributed the rapid shallow breathing to an increased sensitivity of the Hering-Breuer reflex due to the mechanical effects of pulmonary damage.

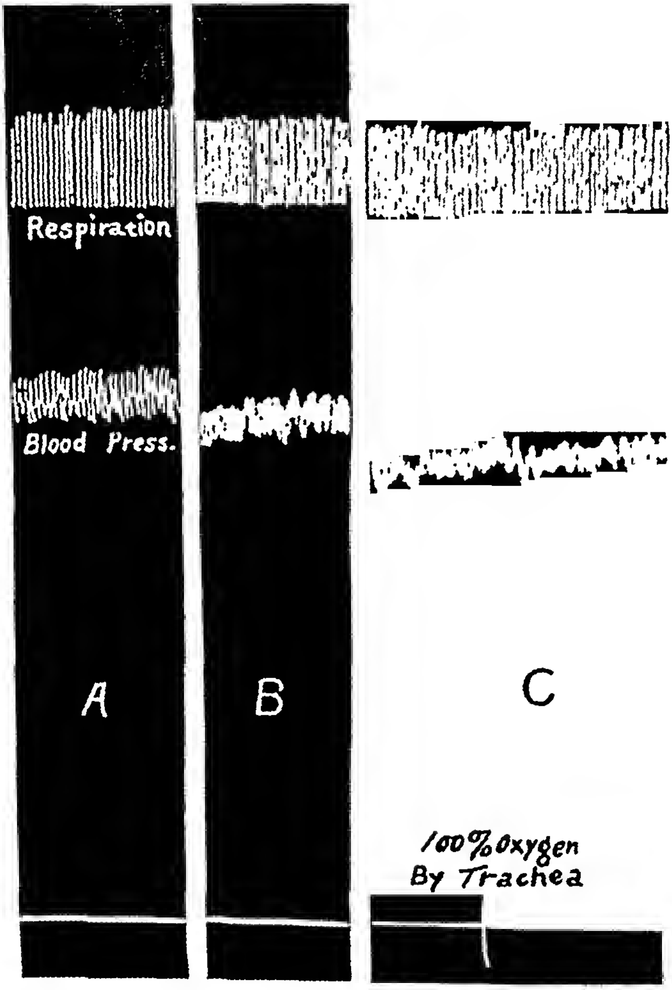

Fig. 3 (Dog 9).—Weight 13 kg. Vagi intact. *A*, Control; *B*, intravenous oxygen 6.5 c.c. per minute; 0.50 c.c. per kilogram per minute; *C*, intravenous oxygen 30 c.c. per minute; 2.3 c.c. per kilogram per minute; 100 per cent oxygen by trachea started at signal.

The respiratory response in our animals with intact vagi also was not primarily due to anoxemia, as demonstrated by Dog 6, in which rapid breathing occurred without the presence of anoxemia, and by Dog 9, in which correction of the anoxemia by the inhalation of 100 per cent oxygen failed to affect the respiratory response (Fig. 3). However, that the response is not entirely a vagal reflex phenomenon arising in the pulmonary tissue is shown by the fact that vagotomy in our animals did not abolish the response entirely, although it changed its character. In these instances, chemical factors were undoubtedly in operation.

From these considerations, the mechanism of the respiratory response to intraveous oxygen apparently depends upon two factors:

1. Pulmonary reflex via the vagi; results in rapid breathing.
2. Carbon dioxide excess and oxygen lack produced by the reduction of the pulmonary capillary bed by multiple gas emboli. According to Schmidt,[7] the typical response to these chemical stimuli is an increased depth of respiration.

In intact animals, the first factor is most important; in vagotomized animals, the second factor is dominant. For example, in Dog 11, which was vagotomized, 100 per cent oxygen by trachea only slightly decreased the respiratory response (Fig. 2). In Dog 12, however, (also vagotomized) 100 per cent tracheal oxygen markedly diminished the hyperpnea (Fig. 4). In the former case, it can be assumed that the respiratory drive was primarily centrogenic, produced by excess carbon dioxide on the respiratory center. In the second animal, which was very deeply anesthetized, the respiratory drive was chiefly reflexogenic due to the effect of anoxemia on the carotid sinus. This latter case is exactly analogous to the "oxygen inhibition" reported by Marshall and Rosenfeld[8] to occur in deeply nembutalized dogs.

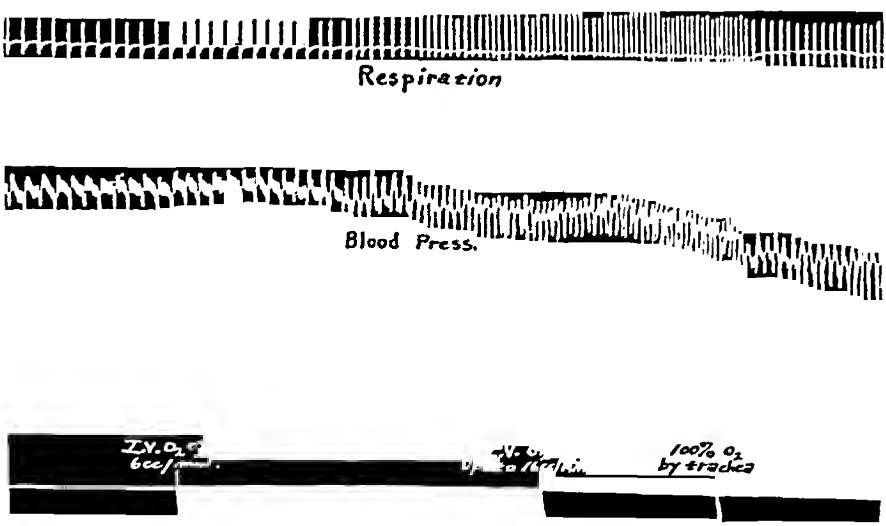

Fig. 4 (Dog 12).—Weight 18 kg. Vagi sectioned. Note inhibiting effect of 100 per cent oxygen by trachea on hyperpnea caused by intravenous oxygen.

2. *Mechanism of the Anoxemia.*—This is probably due to an anoxic anoxia caused by a reduction in the pulmonary capillary bed by multiple gas emboli. The oxygen supplied by vein cannot compensate for the reduced pulmonary supply. With larger amounts, decreased efficiency of the pulmonary circulation due to air bubbles in the right heart is undoubtedly important.

From a therapeutic viewpoint, our results fail to support the claims of Viegler.[1] Intravenous oxygen was not only unable to correct an existing anoxia produced by nembutal anesthesia, but actually increased the anoxemia. That nembutal anoxemia can be corrected by oxygen inhalation has been reported by Schnedorf[9] and McClure and associates,[10] and confirmed by us in Dog 9.

COMMENT

It would appear that if intravenous oxygen therapy will ever prove to be efficient, some way will have to be found so that significant amounts can be administered without causing bubble formation.

SUMMARY

1. Intravenous oxygen in relatively small amounts causes marked respiratory changes, may cause a fall in blood pressure, and usually reduces the arterial oxygen content.

2. The mechanism of the respiratory response and the anoxemia has been discussed.

3. Our results indicate that the intravenous administration of oxygen at rates varying from 0.35 to 2.3 c.c. per kilogram per minute is not only unable to correct an existing anoxemia, but actually aggravates the condition.

AN EFFICIENT APPARATUS FOR THE PREPARATION OF PARENTERAL SOLUTIONS

ALEXANDER G. KELLER, B.Sc., PHILADELPHIA, PA.

AS THE importance of parenteral solutions has grown to such a magnitude during the last ten years, many hospitals have transferred the preparation of these solutions from the operating room staff to the laboratory department, where a special room and personnel are used for the work.

This transfer occurred in our hospital approximately eight years ago, and from one small room we recently expanded to two rooms with a total area of 500 square feet. The rooms are adjoining, one for the cleaning of the glassware and the other for the preparation and bottling of the solutions.

PART I

The cleaning of the glassware is conducted in several steps: (1) the glassware is boiled for fifteen minutes in a detergent solution in a tank; (2) it is thoroughly rinsed with hot tap water for ten minutes; and (3) it is rinsed with distilled water for three minutes (Fig. 1).

For a tank in which to heat the glassware, we use an enameled bathtub. The tub is filled to the overflow level, capacity fifty gallons, with tap water. A wetting agent* is added to remove the hardness of the water and to prevent the formation of a precipitate when the trisodium phosphate is added. Sufficient phosphate is added to give a concentration of approximately 0.5 per cent.

After boiling the glassware the liquid is drained from the tank and the glassware is transferred to the rinsing apparatus. This consists of a shallow bathtub with two pipes, lying lengthwise, on the bottom of the tub. Each pipe has eight vertical nozzles. A wooden rack rests on the pipes, holding a flask mouth down, over each nozzle. By opening a valve, hot tap water enters the two pipes and nozzles and sprays the inside of each flask. The outside of each flask is washed by a rubber tube operated manually by the technician. Finally by closing the hot tap water valve and opening an adjacent valve, distilled water is admitted through the system, and any tap water adhering to the glassware is removed.

In order to have the distilled water under sufficient pressure for the rinsing, we use a vertical style autoclave to which is attached an electric pressure pump.

When the rinsing is completed, each flask is removed and a piece of parchment paper, freshly rinsed with distilled water, is placed over the mouth.

From the Biochemical Laboratories of the Graduate Hospital, University of Pennsylvania.
Received for publication, Sept. 23, 1942.

*Prepared by the Amalgamated Chemical Co. under the trade name Litho Grains No. 2.

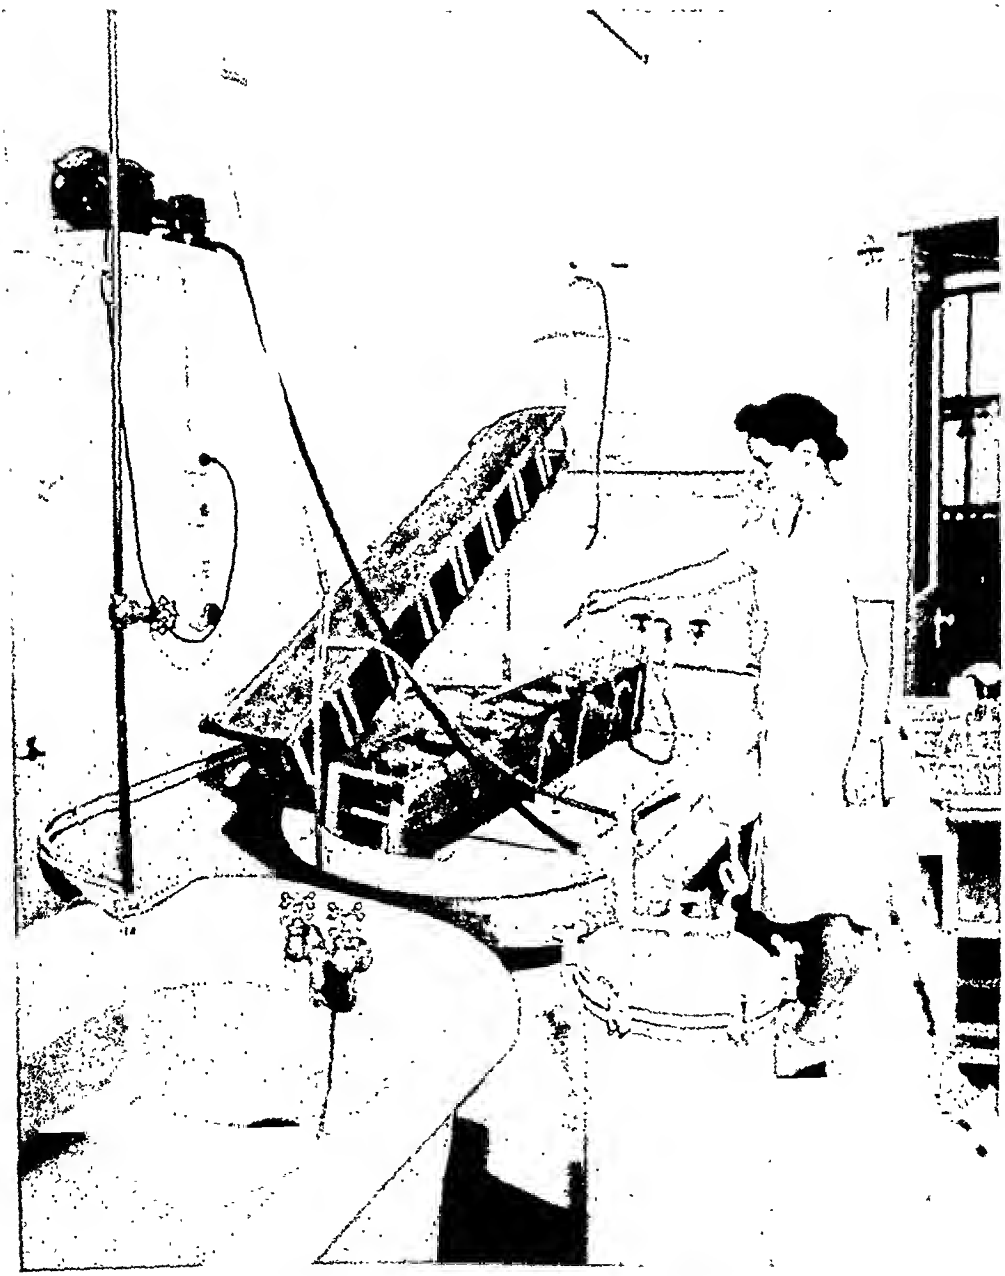

Fig. 1.

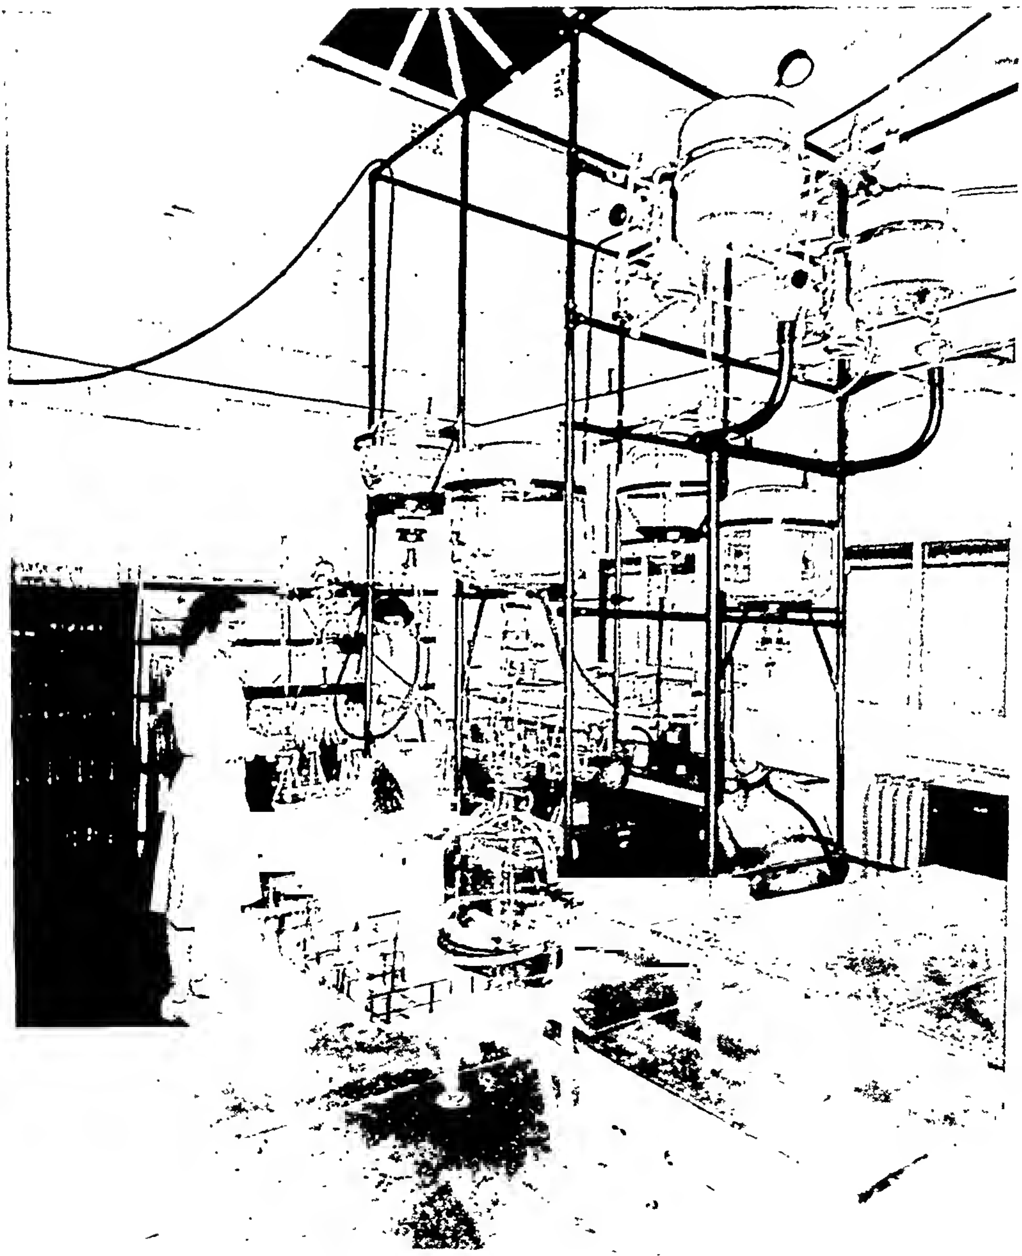

Fig. 2.

PART II

Water is distilled fresh each day by two* five-gallon-per-hour steam-heated stills,* mounted on an iron framework approximately ten feet from the floor (Fig. 2).

The distillate is collected in an inverted twelve-gallon pyrex carboy, mounted in the framework at a level below that of the stills. Directly below this inverted carboy is a second twelve-gallon carboy held in a metal harness attached by a swivel arrangement to the upright on each side. This permits the carboy to be inverted when desired.

The constituents for a parenteral solution are delivered into this lower carboy. The fresh distilled water enters from the upper carboy through a glass tube. In the center of this lower carboy, held in place by the rubber stopper, is a graduated glass tube to indicate the volume of liquid.

Mixing is accomplished by drawing air through the liquid, using a water suction pump. The air is cleaned before entering the liquid by passing through soda lime, weak sulfuric acid, and distilled water.

After mixing, the liquid is drawn by suction through glass tubing to a 50 L. spherical flask adjacent to the upper carboy. In this transit the liquid is filtered through a fritted glass pyrex filter, medium porosity. As a partial vacuum must be created, a spherical flask is used in preference to a standard-shaped bottle. The perforated rubber stopper has a metal disk attached to it on the outside of the flask to prevent the stopper from being sucked in should the vacuum become too great.

The partial vacuum is created by a water suction pump. A glass check valve is placed in the line betwen the pump and the flask to prevent backfire. A gauge is also in the line so the number of inches of vacuum can readily be seen. The vacuum should not exceed fifteen inches. As soon as the spherical flask is half full, the water suction pump is stopped and the vacuum permitted to decline voluntarily. When room pressure is reached, the liquid is permitted to enter the dispensing apparatus.

The dispensing apparatus is essentially a large burette with an overflow. It is operated with pinchcocks and rubber tubing in place of a glass stopcock.

The previously cleaned Erlenmeyer flasks are filled to half their capacity from the dispensing apparatus. The parchment paper cap is replaced, and an additional pleated paper cap or hood, bearing the date of manufacture, is placed over the parchment paper.

After a close inspection to ascertain the presence of any foreign particles in the liquid, two wire ties are placed around the neck of the pleated paper cap and twisted tight.

All solutions are autoclaved the same day they are made. Bactriologic controls are placed in the autoclave at the same time.

A duplicate unit of collection bottle, mixing bottle, spherical flask, etc. is parallel to the first unit described. This permits two different solutions, or two batches of the same solution, to be made simultaneously. The distillate can be delivered to either receiving bottle by opening or closing a pinchcock.

*Made by American Sterilizer Co.

This equipment will produce large quantities of parenteral solutions per day. The iron framework was built by the hospital maintenance department at a comparatively small cost.

No paper filters are used.

The solution is protected from exposure to the air to a great degree.

CONCLUSION

An efficient as well as economical apparatus is described for preparing parenteral solutions.

AN ELECTRIC LANTERN SLIDE POINTER

NELSON A. MURRAY,* M.D., ROCHESTER, MINN.

THIS useful piece of apparatus can be made from odds and ends found in almost any laboratory and will well repay one for the few minutes spent in its construction. The pointer which I made was constructed from the battery case of a Mendelsohn flashlight gun, an adapter for the flashlight bulb, a cardboard mailing carton, two round wooden micro cover slip boxes, and a 7 diopter spectacle lens (Fig. 1). A 7 diopter lens is of approximately 14.28 cm. focal length. This focal length was chosen for no other reason than that it is a convenient length. A lens of 6 or 8 diopters will work equally well.

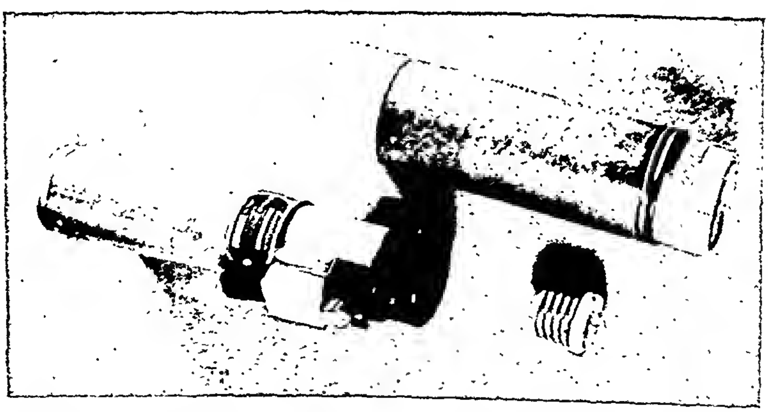

Fig. 1.—Material used in constructing the electric lantern slide pointer.

The lens is placed in front of the flashlight bulb so that the distance between the lens and the light source is slightly greater than the focal length of the lens (Fig. 2). The actual distance can be calculated readily from the standard lens formula. In order to set the lens for a spot at fifteen feet (500 cm.), calculations are as follows: $1/p + 1/q = 1/F$. When $p = 500$ cm. and $F = 14.28$

Received for publication July 27, 1942.

*Fellow in Pathology, Mayo Foundation.

cm., then q = 14.70 cm. Setting the lens at 14.70 cm. from the light source, a small, sharp spot will be focused at approximately fifteen feet. The pointer is adjustable so that by sliding the lens mount (coverslip box) in and out, the distance between the pointer and a sharp focused spot may be varied at will.

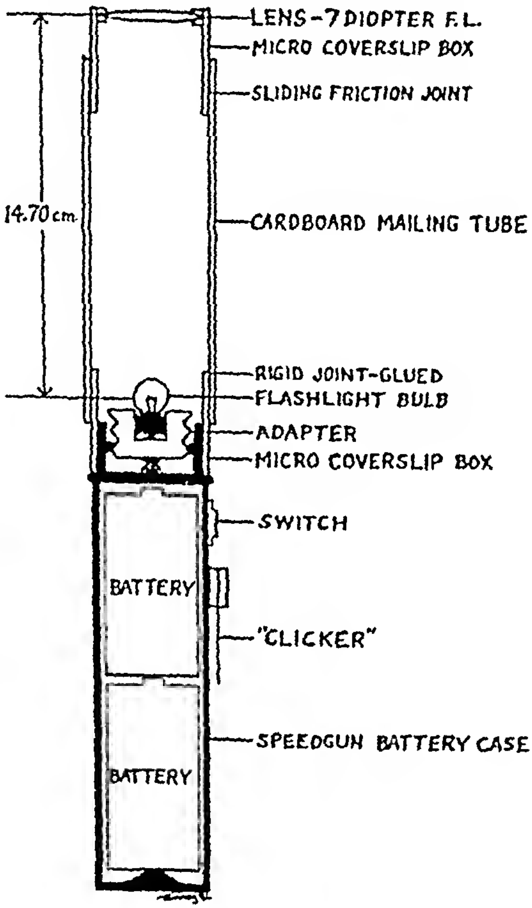

Fig. 2.—Diagram of the electric lantern slide pointer.

A piece of spring steel (slightly bent in the middle by tapping with a machinist's hammer) 1½ by ¾ by 1/32 inch (3.8 by 1.9 by 0.08 cm.) attached to the battery case, as illustrated, emits a "clicking" sound when pressed with the thumb and affords a convenient signal to the lantern operator to change to the next slide. Colored cellophane may be placed behind the lens if a colored spot is desired.

SS AGAR FOR THE ISOLATION OF EBERTHELLA, SALMONELLA, AND SHIGELLA GROUPS FROM FECES*

Compared With MacConkey and Bismuth Sulfite Agars and Tetrathionate Broth Followed by MacConkey Agar†

Mollie Mollov, M.S., Jeanette E. Winter, B.A., and Philip Steinberg, B.S., Jamaica, N. Y.

THE problem of routine isolation of Eberthella, Salmonella, and Shigella organisms from fecal specimens is one of vital importance from a public health standpoint. Detection of the etiologic agents is essential in the diagnosis of enteric bacillary disease and in the recognition of carriers. An efficient selective medium or combination of media is most important for the successful isolation of the incriminating organisms. Many types of media have been devised to facilitate the isolation of these organisms. Few, if any, have proved to be entirely satisfactory for all the enteric pathogens. The medium was often insufficiently inhibitive to prevent overgrowth of the coliform bacilli, or it failed to support the growth of some of the more fastidious organisms.

Liefson,[1] in 1935, devised the desoxycholate-citrate agar as a selective, inhibiting medium which enhanced the isolation of the Flexner type of *Shigella paradysenteriae* bacilli but which inhibited the Shiga, Sonne, dispar and alkalescens strains to a great extent. Paulson,[2] in 1937, found desoxycholate-citrate agar superior to the Endo and eosin-methylene blue agars in bowel disorders. Hardy and Watt[3, 4] confirmed the superiority of the desoxycholate-citrate medium in their experience with their Flexner dysentery cases. They mention, further, that the differential MacConkey agar compares favorably with the Endo and eosin-methylene blue but not with the desoxycholate-citrate agar in the isolation of Flexner dysentery bacilli. Cooper and associates[5] also conclude that MacConkey is superior to Endo and eosin-methylene blue but that desoxycholate-citrate is superior to all three for Flexner and also for Sonne dysentery isolations. Sellers, Morris, and Reynolds,[6] in 1934, found bismuth sulfite agar better than Endo for isolating *Eberthella typhosa*. Gunther and Tuft[7] concluded that bismuth sulfite is superior to Endo, eosin-methylene blue, and desoxycholate-citrate agar in the isolation of *E. typhosa* from urine and feces. Jones[8] found brilliant green-eosin agar superior to MacConkey for dysentery bacilli. Desoxycholate-citrate agar was found to be much better than MacConkey for isolating dysentery bacilli by Irons and co-workers[9] in 1939. Difco Laboratories, Inc.,[10] in 1939, revised their formula for MacConkey agar to support the growth of all the dysentery as well as the typhoid and Salmonella organisms.

*From the Bacteriology Department and the Department of Pathology, Queens General Hospital, Jamaica, Long Island, N. Y.

Received for publication, July 29, 1942.

†SS, bismuth sulfite, and MacConkey agars and tetrathionate broth used in this study were products purchased from the Difco Laboratories.

Studies with SS (Shigella-Salmonella) agar were first reported by Mayfield and Gober[11] 1940. They found SS agar to be as efficient as desoxycholate-citrate for the isolation of dysentery bacilli. They mention, further, that the pathogenic and nonpathogenic* colonies were more clearly defined on the SS medium. Rose and Kolodny[12] confirmed these findings in their studies of Flexner and Sonne dysentery cases. Cooper, Keller and Glesne,[13] in 1942, reported the superiority of SS and desoxycholate-citrate agars over the MacConkey agar in cases caused by *Shigella paradysenteriae* Flexner. They stated, further, that MacConkey was slightly more efficient in isolating Sonne dysentery organisms and also, that although the SS and desoxycholate-citrate agars were equally efficient in the isolation of Flexner dysentery bacilli, a simpler and more distinct differentiation on SS of proteus organisms were present, thus eliminating need for many subcultures.

Several types of *liquid media* have been described to enhance the growth and facilitate the isolation of pathogenic intestinal organisms. In 1936 Leifson[14] described the combination of selenite F enrichment and desoxycholate agar for the isolation of typhoid bacilli. The sodium acid selenite salt favors the growth of typhoid and paratyphoid bacilli and inhibits the coliform organisms. In 1923 Mueller[15] demonstrated that tetrathionate broth, also a selective fluid medium, inhibited the coliform bacilli and permitted the growth of typhoid and paratyphoid bacilli. Kaufman[16] in 1936 increased his positive findings of *E. typhosa* and members of the Salmonella group with this medium. In 1939 Difco Laboratories, Inc.,[17] recommended the use of their tetrathionate broth for enriching stool specimens for the isolation of typhoid, paratyphoid, and dysentery bacilli.

We wish to offer our observations on 501 fecal specimens cultured on SS and MacConkey agars and tetrathionate broth and to compare the findings of our positive cases with the media employed. We wish to report the efficiency of SS agar in isolating many members of the Shigella and Salmonella groups and many strains of *E. typhosa*.

We would also like to mention our results with SS, bismuth sulfite, and MacConkey agars in the isolation of *E. typhosa* from feces in a few known cases of typhoid and one known typhoid carrier.

MATERIAL USED

Fecal cultures of dietary workers, nurses, and interns were examined routinely to rule out carriers of intestinal pathogens. Fecal specimens of hospital cases showing bowel disorders, as diarrhea and the like, were also cultured. In no instance in this study had we any indication in the primary culture of the patient as to whether the specimen contained enteric pathogens. Where no pathogens were isolated from any of the media employed, the case was considered negative either because of the inadequacy of our media or the absence of organisms. The specimen that showed enteric pathogens on all or any of the media employed was considered positive. We wish to compare the results of these positive cases for the evaluation of the media used.

*In this paper, by pathogenic organisms we refer to those belonging to the Eberthella, Salmonella, and Shigella groups.

TECHNIQUE

Fresh fecal specimens were sent to the laboratory in clean paper cups fitted with tight covers. Inoculations were made onto one plate each of SS agar and MacConkey agar and into one tube of tetrathionate broth. Each medium was inoculated separately. A large inoculum was placed on the SS plate and streaked freely over the surface. A large inoculum was put into the 10 c.c. of tetrathionate broth to which was added, just before use, 0.2 c.c. of an iodine solution, which was made up of 5 Gm. of potassium iodide and 6 Gm. of iodine to 20 c.c. of distilled water.* A much smaller inoculum was streaked on the MacConkey agar, often diminishing the inoculum, after making two to three streaks over part of the surface by cutting through the agar with the platinum wire at the outermost edge of the medium and then continuing to streak over the unused surface of the plate. All three media were incubated at 37° C. The agar plates were read after eighteen to twenty-four hours, and the number and character of the nonlactose-fermenting colonies on each solid medium were noted and recorded. Two to four of each type of nonlactose fermenting colony were fished to Krumweide sugar slants from each plate. The tetrathionate broth was streaked to MacConkey agar after incubation. This plate was in turn incubated overnight and treated as the initial agar plates. One Krumweide triple sugar slant from each case, giving typhoid, paratyphoid, or dysentery reactions was studied in detail. The other Krumweide slants were kept at icebox temperature until the identification of the slant was completed. Subcultures were made to phenol red broth fermentation tubes (lactose, saccharose, dextrose, mannitol, maltose, sorbitol, dulcitol, salicin). Tryptone broth was inoculated for indol production. Motility tests were done on young cultures from nutrient broth. Motility test medium, a semisolid agar† was used when broth cultures failed to show motility. Fermentation tests were read at twenty-four and seventy-two hours and then intermittently for ten days. All Shigella organisms were idenified serologically by us and checked by the New York City Health Department. The Salmonella organisms were identified serologically by the International Salmonella Committee at the Beth Israel Hospital, New York. All final identifications were based on cultural and serologic findings. The organism from one Krumweide slant from each specimen was studied in detail. However, if the first Krumweide triple sugar slant chosen gave atypical reactions, another slant, fished at the same time from another suspicious colony, was carried through the same procedure detailed above.

In our studies of the known typhoid cases and the known typhoid carrier, in addition to the SS and MacConkey media, a bismuth sulfite agar plate was used. A large inoculum was streaked freely over the entire surface of the medium, and the plate was incubated at 37° C. for forty-eight hours. This plate was then examined, two to four characteristic black colonies were fished to Krumweide triple sugar slants, and the same procedure as described above was followed.

RESULTS

Five hundred and one unknown fecal specimens were examined. Three hundred and thirty-three were from dietary workers, nurses, and interns ap-

*Recommended by the Difco Laboratories, Inc.
†Difco Laboratories, Inc.

parently in good health. One hundred and sixty-eight were from hospital patients with possible intestinal disorders. Of the 333 specimens mentioned above, fourteen specimens were positive. These were isolated from five individuals who were now labelled carriers of typhoid, Sonne, atypical dysentery one case each), and alkalaseens (two cases each). For purposes of studying the efficiency of the culture media employed, we are listing each specimen as a separate case. Of the 168 hospital cases, twenty-six specimens were positive from sixteen cases. Table I lists the types of organisms in the Eberthella, Salmonella, and Shigella groups found to grow on SS agar and also compares the nonlactose fermenting colonies noted in each case, quantitatively, on each type of medium used in this study. It is significant to note that *of the forty positive cases listed, thirty-four were isolated on SS agar only, twenty-seven in tetrathionate broth followed by MacConkey agar, and seventeen on the MacConkey*

agar. In eight cases, the SS agar only was positive, and in five instances, only the tetrathionate picked up the intestinal pathogens. In two of these five cases, the SS and MacConkey agars were overgrown by coli because too large an inoculum was used. In one case only was the MacConkey plate alone positive. It will be noted further that SS was as efficient or superior to MacConkey for all but one case of typhoid and for many types of Shigella and Salmonella. Table II illustrates the total number and percentage of positive cultures on the various media used, and Table III illustrates the number and percentage of positive findings with the various combinations of the three media.

TABLE II

NUMBER OF PERCENTAGE OF POSITIVE CULTURES WITH THE VARIOUS MEDIA

ORGANISMS	TOTAL NUMBER	NUMBER OF POSITIVE CULTURES ON		
		SS	MAC	TETRA

S. montevideo	1	0	0	1
S. newport	1	1	1	1
S. cholerae suis var Kuzendorf	1	1	1	1
S. typhi murium	1	1	1	1
S. oranienberg	4	3	1	4
S. urbana	1	1	1	1
S. derby	1	0	0	1
Total positive cultures	40	34	17	27
Per cent of positive cultures	100	85	44.4	67.4

TABLE III

COMPARISON OF TOTAL POSITIVE FINDINGS WITH EACH MEDIUM AND WITH VARIOUS COMBINATIONS OF MEDIA

	TOTAL POSITIVE	PER CENT POSITIVE
SS agar	34	85.0
SS plus MacConkey agar	35	87.5
SS plus tetrathionate broth	39	97.5
MacConkey agar	17	44.4
MacConkey agar plus tetrathionate broth	29	72.5
Tetrathionate broth	27	67.4
SS and MacConkey agar and Tetrathionate broth	40	100.0

It is of interest that SS agar aided in the diagnosis of 85 per cent of the positive cases, and the combined use of SS agar and tetrathionate broth allowed successful isolations in 97.5 per cent of the studied cases. In contrast, we find MacConkey agar successful in the isolation of 44.4 per cent of the cases, and the combined use of MacConkey agar and tetrathionate broth successful in 72.5 per cent of the cases studied. It is of significance that SS agar in conjunction with tetrathionate broth allowed us to diagnose all but one of these forty cases.

DISCUSSION

We have run the gamut of culture media for the detection of intestinal pathogens from feces in our laboratory. As a differential medium, MacConkey agar was found to be superior to eosin-methylene blue and Endo (the two most

commonly used types of media). This is in agreement with the published results of Hardy and Watt, Cooper and co-workers, and others. It is the most clear-cut differential medium so far described which supports the growth of all intestinal pathogens and coliform bacilli. The coli colonies are brick red surrounded by a zone of precipitated bile. The colonies of Eberthella, Salmonella, and Shigella are uncolored and transparent and appear as clearing areas in the precipitated bile, caused by the coliform organisms. This makes possible a clear-cut reading when the plate is not overcrowded.

As a selective inhibitive medium we have found the SS agar superior to desoxycholate-citrate (unpublished). This is also in agreement with Mayfield and Gober and others. The SS medium gives maximum inhibition of coli with minimum restriction of the intestinal pathogens. It was found to support the growth of strains of Flexner, Sonne, alkalescens, and an atypical dysentery organism, many strains of *E. typhosa,* and a long list of many types of Salmonella, such as *S. newport, S. montevideo, S. cholerae suis* var. Kunzendorf, S. typhi murium, S. oranienberg, *S. urbana, S. schottmülleri,* and *S. derby.* This is an obvious advantage. Desoxycholate-citrate agar is recommended for the isolation of Flexner and Schmidt's dysentery bacilli but which restricts the growth of Shiga, Sonne, and alkalescens types of paradysentery bacilli. Bismuth sulfite is recommended to be superior to desoxycholate-citrate, eosin-methylene blue, and Endo agars for the isolation of *E. typhosa.*

In a very small series of known cases and one carrier of typhoid we have compared bismuth sulfite, SS and MacConkey agars. In all but one case have we found SS as efficient or superior to bismuth sulfite agar in isolating *E. typhosa* from feces, and in that case the MacConkey agar was also positive. Further study with these three media will be reported in a subsequent paper.

In SS agar we therefore find an excellent selective and advantageous inhibitive medium for the isolation of Eberthella, Salmonella, and Shigella organisms. It readily differentiates these three groups and other nonlactose-fermenting organisms which form opaque, transparent, or translucent uncolored colonies from the brick red-colored coli. Of all the inhibitive, selective media thus far described, SS is one medium which is sufficiently inhibitive to allow a large inoculum and which supports the growth of all intestinal pathogens found in these studies.

The tetrathionate broth has been very useful. In five of the thirty-one positive findings, the organisms were picked up only in the tetrathionate broth. In three of these cases no pathogens were seen in either of the agars used. In two cases, both the SS and MacConkey plates were overgrown by coli. Where there exist too few organisms in the specimen to be recognized on agar, they may multiply in the tetrathionate broth, which inhibits the coli, and then on subculture, from this broth, the pathogens may be more easily isolated. It is also of value in cases where, unfortunately, too large an inoculum is used on solid media and, as a result, discrete colonies are not obtained. Tetrathionate broth was found to support the growth of many strains of Salmonella, Shigella, and Eberthella as listed in Table I.

CONCLUSION

1. SS agar is an excellent culture medium for isolating Eberthella, Salmonella, and Shigella from feces. It gives fine definition of colony, provides for maximum inhibition of coli, and facilitates isolation of intestinal pathogens when a large inoculum is used.

2. If one selective, inhibitive, solid medium were to be chosen for the isolation of all intestinal pathogens, SS agar would seem to be best choice thus far.

3. In conjunction with SS agar, tetrathionate broth is of definite value in the isolation of Eberthella, Salmonella, and a few of the Shigella group.

4. In a small series of positive cases, SS agar was found as efficient or superior to bismuth sulfite agar in the isolation of *E. typhosa* from feces.

We wish to thank Dr. Alfred Angrist, Pathologist of Queens General Hospital, for his many helpful suggestions and kind cooperation.

CHEMICAL

SOME SOURCES OF ERROR IN SULFANILAMIDE DETERMINATIONS*

A. H. S. Holbourn, M.A., D.Phil., and R. E. Pattle, B.A.
Oxford, England

THE METHODS commonly adopted for the determination of the concentration of sulfanilamide in blood are liable to errors arising from the neglect of certain variables which strongly influence the values obtained. Until these variables were tracked down, and the errors due to their neglect eliminated, inconsistent results were obtained.

A number of modifications of Marshall's[1] original method have been proposed. But, as will be shown later, these have little or no effect on the errors with which this paper is concerned. These errors arise, for the most part, during the diazotization of the sulfanilamide, and, as the modifications to the original method are mainly concerned with procedures subsequent to diazotization, they do not remove the errors which have already occurred.

As the particular method employed is therefore unimportant, a simple method, based on Marshall's original method, was used wherever possible. The exact procedure is described in the manual of the Evelyn photoelectric colorimeter as follows:

Take 0.2 c.c. whole blood, and add 7.8 c.c. distilled water. Allow to stand for two minutes. Add 2 c.c. 15 per cent toluenesulfonic acid. Mix well and filter. Pipette 4 c.c. of filtrate into a colorimeter tube, add 1 c.c. of 0.025 per cent sodium nitrite solution, mix well and stand for three minutes. Add 5 c.c. of a solution consisting of 1 c.c. dimethyl-α-naphthylamine in 250 c.c. ethyl alcohol. Read the color developed after ten minutes against a blank made up with 4 c.c. of 2.5 per cent toluenesulfonic acid instead of 4 c.c. of filtrate.

Determinations were also made using 10 per cent trichloracetic acid as a protein precipitant instead of toluenesulphonic acid, and 2 per cent trichloracetic acid in the blank instead of 2.5 per cent toluenesulfonic acid.

The sulfanilamide which was the subject of this investigation was added to the distilled water used for hemolyzing the blood in an amount equivalent to a concentration in the blood of 10 mg. per 100 c.c. Human blood, kept fluid by the oxalate crystal method, was used. A filter having a maximum transmission at 520 mμ was used in the colorimeter.

The most important of the numerical results on which the findings below are based are given in Table I. In the column headed "Density" is given 23.8

*From the Nuffield Department of Surgery, University of Oxford, England.
Received for publication, July 28, 1942.

TABLE I

TEMP. OF DIAZOT'N	DENSITY 3 MIN. DIAZOT'N		DENSITY 10 MIN. DIAZOT'N		DENSITY 20 MIN. DIAZOT'N		DENSITY 6 HR. DIAZOT'N	
	T.S.A.	TRICHL.	T.S.A.	TRICHL.	T.S.A.	TRICHL.	T.S.A.	TRICHL.
0° C.	3.5	4.3			9.2	9.7	9.7	
10°	5.7	7.2	9.3	10.0	10.3	10.5		
20°	9.0	9.7	9.7	10.0	10.0	10.0		7.0
40°	9.6	10.0			9.1	10.0		
20° DS	6.5	8.6			0.3	5.4		
20° PS20					10.0	10.0		
20° PS180					3.1	9.0		
20° U	7.4				9.0			

DS means that the diazotization was carried out in sunlight.

PS20 means that after the pink color had developed completely, it was exposed to 20 minutes of sunshine.

PS180 means that after the pink color had developed completely, it was exposed to 8 hours of sunshine.

U means that the nitrite was gently run in and not stirred.

$(2 - \log_{10}G)$, where G is the percentage transmission of the colorimeter tube. The effects of the following variables were studied.

The Effect of Light on the Diazo Reaction.—There was no perceptible difference between diazo reactions which proceeded in the dark and reactions which proceeded five feet away from a 60 watt bulb in a pearl glass shade, under any conditions of temperature or time of diazotization. But the effect of direct sunlight was very pronounced. The sun, in these experiments was always shining from a clear sky, but, unfortunately, this varied considerably in blueness, so that the different densities in the table are not strictly comparable. How important the effect of sunlight can be under certain conditions is shown by the fact that one solution which had been diazotized for twenty minutes in strong sunlight failed to produce any color at all when coupled to dimethyl-α-naphthylamine in the dark. Coupling to N-(1-naphthyl)ethylenediamine, instead of dimethyl-α-naphthylamine after twenty minutes' diazotization in sunlight caused a very faint yellowish color to appear instead of the usual purplish pink color. As one would expect, the effect of sunlight is less pronounced if one diazotizes in sunlight for only three minutes.

Once the diazo compound has been coupled to dimethyl-α-naphthylamine, and the pink color completely developed, twenty minutes' exposure to sunlight has no appreciable effect, although eight hours' exposure changes the pink color to a brownish yellow. According to Bratton and Marshall,[2] the purplish pink ethylenediamine compound is decomposed by sunlight.

Time and Temperature of Diazotization.—All the following results were obtained when the diazotization and the coupling were carried out in artificial light.

For temperatures of diazotization between 0° and 20° C., approximately the same maximum color was obtained on coupling if the diazotization had been carried out long enough. For temperatures between 10° and 20° C., ten minutes was sufficient to produce maximum color when trichloracetic acid was used as the precipitant, and twenty minutes when toluenesulphonic acid was used. A three-minute diazotization did not produce maximum color unless the temperature was raised to 30°. Too high a temperature or too long a time of diazotization produced some destruction of the diazo compound.

The Protein Precipitant.—It was found that with times and temperatures of diazotization which were insufficient to produce maximum color, trichloracetic acid produced somewhat denser color than toluenesulfonic acid. But when the time and temperature were sufficient to diazotize the sulfanilamide fully, the same color density was developed in the presence of either precipitant. With trichloracetic acid, diazotization was more rapid and it was less affected by sunlight, too high a temperature and too long a time of diazotization. Hence, from this point of view, trichloracetic acid is preferable as a precipitant.

The Keeping Qualities of Sulfanilamide in the Presence of Trichloracetic Acid or Toluenesulfonic Acid.—The sulfanilamide content remained constant when the protein free filtrate was kept in the dark at room temperature for fourteen days, with either precipitant.

The Keeping Qualities of the Alcoholic Solution of Dimethyl-α-Naphthylamine.—Perfectly consistent results could be obtained with a solution which had been kept at room temperature for a month. The solution became slightly brownish in this time, but, provided the blank was also made up with this brownish solution, the same readings for density were obtained as with a clear, fresh solution.

The Keeping Qualities of the Pink Dye.—Provided the diazotized sulfanilamide was coupled to the dimethyl-α-naphthylamine in moderate artificial light, full color developed in about ten minutes, for temperatures of coupling between 0° and 20° C. All readings were therefore taken after ten minutes. Even after keeping the pink dye in the dark at room temperature for a week the color was only just measurably darker than after ten minutes.

Improper Mixing of the Nitrite.—If the nitrite was not properly mixed with the protein free filtrate, diminished color was obtained even after a twenty-minute diazotization.

The Dilute Sodium Nitrite Solution.—The dilute nitrite solution (0.025 per cent) was always freshly made up each week from a 1 per cent stock solution. But it was afterwards found that some 0.025 per cent solution of ordinary sodium nitrite which had been kept in the dark for four months gave the same results as freshly made up solution, for concentrations of sulfanilamide equivalent to 10 mg. and also to 30 mg. per 100 c.c. Some dilute nitrite solution which had stood close up againest a window for three months also gave the same results for 10 mg. per 100 c.c. No test was made with this nitrite solution on any stronger solution of sulfanilamide.

There was no difference in the results obtained when using A.R. sodium nitrite, and the results when using ordinary sodium nitrite.

Excess Nitrite and the Effect of Sunlight.—A very large excess of nitrite, say fifty times the usual excess, will inhibit the formation of the pink dye and lead to the formation of a yellowish color instead. Hence the excess nitrite is often removed with urea. When 1 c.c. of 0.25 per cent urea solution was added to a trichloracetic acid and sulfanilamide mixture which had been diazotized for twenty minutes in very strong sunlight, and the whole allowed to stand for one minute before coupling, practically no color was developed. Exactly the same low color density was obtained when the 1 c.c. of urea solution was replaced by 1 c.c. of distilled water. It was also found that when diazotization

had been carried out in the dark, the effects of 1 c.c. of urea solution and 1 c.c. of distilled water were exactly the same.

Use of N-(1-Naphthyl) Ethylenediamine.—Where a twenty-minute diazotization had taken place in very strong sunlight, a pale yellowish color developed on coupling to N-(1-naphthyl)-ethylenediamine instead of the usual purplish pink color. The removal of the excess nitrite did not change this color in any way. Similarly, when the diazotization was carried out in the dark, the removal of the excess nitrite had no effect.

DISCUSSION

Our results differ from those of previous workers in certain particulars of practical importance.

The most important result is the effect of sunlight on the diazo reaction. This does not seem to have been noticed before, possibly because diazotization for only three minutes is the usual practice. Unless the light was strong its effect in this amount of time might escape detection. Nevertheless the effect of light in tropical countries under camp conditions would be of the utmost importance whatever the time of diazotization.

Marshall[3] found that diazotization of sulfanilamide was practically complete in one minute, and no significant difference in color was obtained if the reaction was allowed to proceed for eight minutes. This does not agree with our results. A possible explanation is that Marshall's work may have been carried out at a room temperature considerably higher than usually obtains in Britain.

It is the general practice in diazotization to keep the temperature below 5° C., as most diazo compounds decompose rapidly above this temperature. The naphthylamines and nitroanilines, however, may be diazotized at room temperature without loss of yield. Sulfanilamide also appears to have a diazo compound which is comparatively thermostabile.

As, in our experiments, only free sulfanilamide was present, our results refer strictly only to free sulfanilamide determinations. Methods of determining total sulfanilamide are described by various workers. They are similar to the method given, except that the sample of blood or the protein free filtrate is boiled for about an hour either with the protein precipitant or with hydrochloric acid. This has little effect on subsequent operations, so that our results may be taken as applying without serious modification to determinations of total sulfanilamide.

We found that both trichloracetic acid and toluenesulfonic acid are satisfactory as protein precipitants. Marshall[3] found that both were satisfactory for free sulfanilamide, but that trichloracetic acid was unsatisfactory for total sulfanilamide because, owing to the decomposition taking place during boiling, it did not fully hydrolyze the conjugated compound. Hence Abrahamson[4] boils the filtrate with hydrochloric acid after precipitating the proteins with trichloracetic acid.

Marshall[1] recommends that the dilute nitrite solution should be freshly prepared, and that exceedingly pure nitrite should be used. We find these precautions unnecessary.

Marshall and Litchfield[5] propose certain improvements in the method, viz., removal of excess nitrite with ammonium sulfamate, and buffering of the reaction mixture with acid sodium phosphate. Ratish and Bullowa[6] use urea to remove the excess nitrite. We have found that the moderate excess of nitrite recommended in Marshall's original paper has no measurable effect in any circumstances in which we have made tests. It would certainly be surprising if, when the diazotization is incomplete due to too low a temperature or too short a time of diazotization, the removal of the excess nitrite or of any other of the suggested modifications of the original method completed the diazotization. Hence the time and temperature relationships given in Table I will remain the same.

In their latest method Bratton and Marshall[2] use N-(1-naphthyl)-ethylenediamine as coupling agent. Here they note the effect of light on the completed dye, but not on the diazo compound.

Marshall, Emerson and Cutting[7] find differences of 2-3 per cent between duplicate determinations. The figures given in the table have at least this degree of accuracy.

CONCLUSIONS

The generally recommended precautions have little or no effect in remedying the errors which often arise in the measurement of sulfanilamide. These errors are usually due to the fact that the diazo compound of sulfanilamide is very easily decomposed by light, and to the fact that, unless the room temperature is very high, diazotization is incomplete in three minutes, which is the usual time.

If the diazotization is incomplete, its dependence on time and temperature is very marked. Hence in order to avoid the necessity of accurate control of both the time and the temperature, the diazotization should proceed until it is as nearly complete as possible. Therefore, if trichloracetic acid is used as the protein precipitant, diazotization should proceed for ten minutes at temperatures between 0° and 30° C., but if toluenesulfonic acid is used, twenty minutes is necessary.

SUMMARY

When sulfanilamide is estimated by forming a diazo compound and coupling to dimethyl-α-naphthylamine or N-(1-naphthyl)ethylenediamine, it is recommended that the diazo reaction should proceed at room temperature in moderate artificial light for ten minutes in the presence of 10 per cent trichloracetic acid. With 15 per cent toluenesulfonic acid twenty minutes is necessary. The coupling reaction should also be performed in moderate artificial light.

The effect of sunlight might be very important when making determinations in tropical countries under camp conditions.

We should like to thank Mr. O'Brien and Mr. Higgins of the Radcliffe Infirmary for their valuable criticisms and assistance.

A SIMPLE CHAMBER FOR ESTIMATION OF SERUM pH WITH A GLASS ELECTRODE*

Alfred H. Free, Ph.D., Cleveland, Ohio

THE development of the glass electrode has led to its widespread use in the determination of pH or hydrogen ion concentration.[1] This electrode has been successfully employed in the measurement of the pH of blood, serum and plasma.[2-4] Recently many manufacturers of laboratory apparatus have placed on the market portable pH meters which are adapted for use with glass electrodes.

In the estimation of pH of blood, serum or plasma it is essential that the measurements be carried out in a closed chamber to prevent loss of CO_2 which will in turn cause changes in pH. Methods of handling blood to prevent CO_2 losses have been adequately discussed.[5, 6] The present report describes a simple chamber which can be used with a glass electrode in the determination of pH of blood serum.

Description of Chamber.—The chamber is made from a four-way glass stopcock in which the four outlets are in the same plane at right angles to one another. The plug of the stopcock has a bore such that any two adjacent outlets can be connected. The outlet tubes have an internal diameter of 1 mm. and 6 mm. external diameter and the plug of the stopcock has a 1 mm. bore. Such stopcocks are available from manufacturers.†

Onto one of the outlet tubes (Outlet II) is fused a larger tube which has a length of 30 mm. and an inner diameter of 13 mm. A larger tube (10 mm. inner diameter and 15 mm. long) is also fused onto the adjacent outlet (Outlet III) which is then bent at right angles as shown in the photograph (Fig. 1).‡

The chamber can conveniently be seated and fastened with rubber bands to a prong of wood which is attached to a small ring stand. The bulb type glass

‡A chamber with these specifications was made for the author by the Dietz Chemical Glass Works, Inc., 1975 E. 65th St., Cleveland, Ohio.

electrode is fitted into the upper chamber of Outlet II by means of a rubber collar placed around the neck of the glass electrode. This collar can conveniently be made from a rubber stopper or a piece of pressure tubing and should be airtight. A piece of 20 gauge syringe needle is placed through the collar to serve as a gas exit. This exit can be readily closed by sticking a small cork on the needle as is shown in the photograph. The calomel half cell is connected to the side chamber by means of a rubber stopper. A small piece of rubber tubing is connected to the horizontal outlet tube (Outlet I). When the glass electrode and calomel cell are connected to the pH meter the instrument is ready for use.

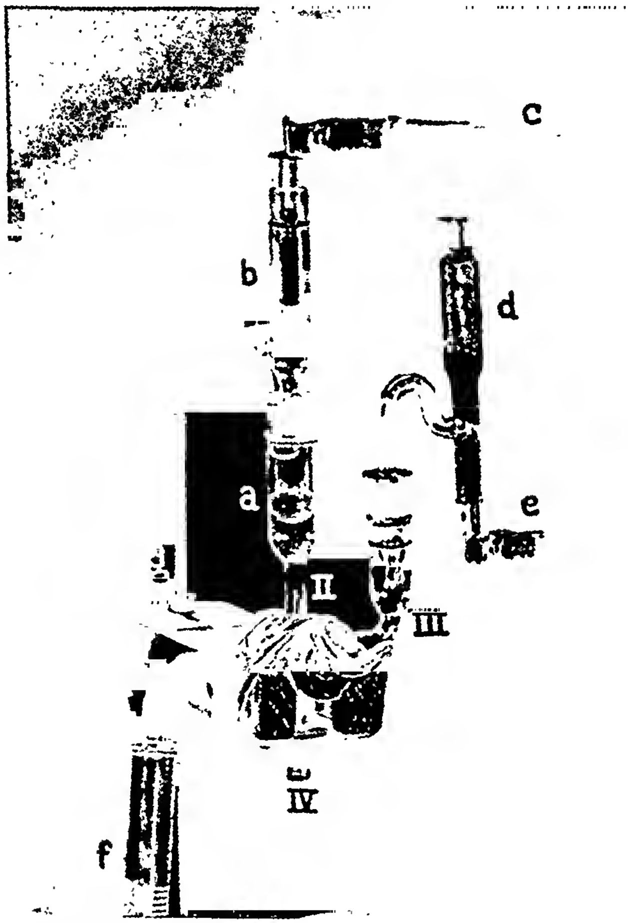

Fig. 1.—Chamber for determination of serum pH. *I*, Stopcock Outlet I for introducing serum sample. *II*, Stopcock Outlet II containing chamber into which bulb type glass electrode is inserted. *III*, Stopcock Outlet III containing chamber for attaching calomel half cell. *IV*, Stopcock Outlet IV which serves to carry away waste KCl and waste mineral oil. *a*, Chamber containing serum ready for measurement. *b*, Glass electrode. The bulb can be seen in the serum chamber. *c*, Lead to pH meter from glass electrode. *d*, Hellige calomel half cell. *e*, Lead from calomel half cell to pH meter. *f*, Syringe in position for introducing sample. *g*, Ring stand with small prolonged wooden block for holding chamber.

The chamber described has been used exclusively with a Hellige pH meter,* a Hellige calomel half cell, and a Hellige bulb type glass electrode (diameter of bulb 10 mm.). However, so far as can be ascertained, there is no reason why the apparatus could not be used with other instruments. It would no doubt be desirable to change the size and shape of the chamber housing the glass electrode if the glass electrode used were of a different design.

*Hellige electrometric pH meter with range control.

Method for pH Determination.—Using a 5 c.c. syringe which contains about 1 c.c. of mineral oil and no air bubbles, 2 c.c. of serum is drawn into the barrel of the syringe. The syringe is inverted so that the oil rises to the top and the needle is removed. The syringe is connected with the rubber tube on Outlet I and the stopcock turned to connect Outlets I and IV. With the syringe still inverted the oil is discharged through Outlet IV into a waste container. By carrying out this operation slowly the stopcock can be turned to connect Outlets I and II as soon as serum reaches the stopcock. The serum is forced into the chamber housing the glass electrode. The stopcock is then turned an eighth of a revolution to the right and a small cork placed over the end of the syringe needle which serves as a gas exit. The stopcock is then turned to connect Outlets II and III and the reading of the pH is made in this position. The stopcock is then turned to connect Outlets III and IV and approximately 2 c.c. of saturated KCL solution allowed to flow through the calomel half cell and out into a waste container. The serum is then allowed to flow out of the chamber by turning the stopcock to connect Outlets I and II and removing the stopper from the needle.

It has been found that if the serum drains completely there is no necessity to rinse out the serum chamber when a series of serum pH determinations are being made and the variation between samples is not more than 0.15 pH. It has furthermore been found that the loss of CO_2 from the serum when it is being introduced into the chamber is negligible. This has been found by introducing a sample and measuring its pH and subsequently withdrawing it through the needle exit while the second sample of the same serum is simultaneously being introduced. By this technique duplicates check to within 0.01 pH as they do when carried out in the conventional manner.

With care mineral oil can be kept out of the chamber and hence off the glass electrode. However, a small amount of oil deliberately introduced into the electrode chamber does not give a value different from a duplicate in which no oil is present.

For serum pH studies a convenient reference buffer is a ⅟₁₅ M. phosphate buffer with pH of 7.38 at 38° C.[7] The buffer is standardized by exactly the same operations used for the serum.

In order to avoid temperature corrections the chamber and electrode system as well as the pH meter are kept at 38° C. This has been accomplished by keeping the whole outfit in a room at 38° C. or by placing the outfit in a large thermostat box maintained at 38° C.

SUMMARY

A simple chamber made from a four-way glass stopcock has been described for use with a glass electrode and pH meter in the determination of serum pH. The technique for measurement of serum pH with the chamber is described.

NOTE ON THE DETERMINATION OF "CITRIN" IN LEMON PREPARATIONS*

Arthur E. Goldfarb, M.D., Ernest Bueding, M.D., and Philip Karp, B.S.
New York, N. Y.

THE expanding use of lemon extract containing so-called "Vitamin P" or "lemon citrin" in the treatment of psoriasis[1] makes it of interest to determine the "citrin" content of the lemon preparation used.

It was observed that in the determination of "citrin"[2] the reddish-brown color produced by addition of alkali to lemon preparations was increased by heating the samples for two minutes at 100° C. Since carbohydrates produce a brown color on heating with alkali (Moore's reaction), it was investigated whether the presence of sugar interferes with the determination of "citrin," and an attempt was made to eliminate this possible source of error.

The preparation of lemon extract was essentially the same as described by Lorenz and Arnold,[2] except that in one series of experiments the lemon peel was extracted without cooking.

Procedure.—In modification of the method described by Lorenz and Arnold,[2] the following procedure was used for the assay of "citrin" in lemon preparations:

To the solution to be analyzed, an equal volume of alcohol (95 per cent) is added and the mixture filtered. The filtrate is diluted with 50 per cent alcohol so that the color intensity lies within the optimum range of standard eriodictin solutions (lemon peel extract 1:100, lemon juice 1:20, final product being a mixture of both, 1:50). Eight-tenths c.c. of 25 per cent KOH is then added to 9.2 c.c. of this dilution and the color produced is read in the Klett-Summerson colorimeter using filter No. 42, at which time maximum color development occurs.

*From the Departments of Dermatology and Medicine, New York University, College of Medicine, the Dermatological Service of the Third (New York University) Medical Division, and the Medical Service of the Psychiatric Division, Bellevue Hospital, New York City.

Aided by a grant from The California Fruit Grower's Exchange, Inc., Mr. Anthony J. Lorenz—Director of Research.
Received for publication, Sept. 18, 1942.

Determinations of eriodictin solutions (A52) of known concentration showed that the optimum range falls between 0.04 and 0.2 mg. eriodictin per cubic centimeter in which a straight-line relationship is observed between concentration and colorimeter reading.

Effect of Glucose on Colorimetric Determination of "Citrin."—It was found that both lemon juice and lemon peel extract contain about 1 per cent of fermentable reducing monosaccharides. While this amount of glucose (0.05 per cent in a dilution of 1:20 of lemon juice) when added to standard eriodictin solutions does not produce any color reaction, a measurable color is produced with the above procedure after heating for two minutes. On the other hand, in all lemon preparations the apparent "citrin" value was higher after heating for two minutes than in the unheated sample. This indicates that on heating the samples, glucose and possibly other substances interfere with the "citrin" determination and, therefore, give higher values than correspond to the true "citrin" content of the lemon preparation.

Effect of Cooking on "Citrin" Content of Lemon Peel Extract.—The colorimetric determination of the cooked extract gives significantly lower values than the uncooked, indicating that some "citrin" is destroyed on cooking. The uncooked extract was obtained by allowing the ground peel to stand in cold water at room temperature for twenty-four hours or more.

"Citrin" Content of Lemon Juice.—A measurable quantity of "citrin" can be found in lemon juice; its concentration is about one-sixth of that contained in the uncooked peel extract. Whether the compound found in lemon juice has biological activity is yet to be determined.

When lemon peel extract and juice whose "citrin" contents have been determined separately are combined, the determination of this mixture yields the "citrin" value calculated from the figures for each component.

SUMMARY

1. A modification of the method of Lorenz and Arnold for the determination of "citrin" in lemon preparations is described, and the interference of glucose is eliminated by avoiding heating of the solutions after the addition of alkali.

2. A more efficient extraction of "citrin" from lemon peel is obtained by extracting in the cold instead of by cooking.

3. Lemon juice contains about one-sixth the amount of "citrin" found in lemon peel extract.

DETERMINATION OF URIC ACID IN WHOLE BLOOD AND SERUM*

J. W. MULL, PH.D., CLEVELAND, OHIO

A STUDY of the uric acid content of the blood was undertaken with the threefold purpose of selecting a practical method for clinical determinations using a photoelectric colorimeter, establishing the normal range for uric acid by this method, and ascertaining the relation between the uric acid content of whole blood and of serum.

The colorimetric method of Benedict and Behre[1] on the silver chloride filtrate, while a most satisfactory method for a visual colorimeter, is unsuited to the photoelectric colorimeter since it must be read while hot. The method proposed by Brown[2] depends on exact timing, and with the great sensitivity of the photoelectric instrument the changes are so rapid as to preclude reading checks. That of Newton,[3] in addition to rather elaborate reagents, did not give a curve that could be duplicated with successive determinations on the standard. Although Folin's method,[4] permits the development of the color at room temperature, it requires too much time in the preparation of reagents to be available for clinical use. We therefore turned back to the simple, short, but direct method of Benedict,[5] to which we applied the uricase treatment of Blauch and Koch.[6] Since uricase destroys uric acid, the color developed after the addition of uricase represents impurities. This value subtracted from the untreated findings gives the true uric acid content.

METHOD

To separate 1 c.c. samples of whole blood and serum was added 25 mg. uricase powder. The tubes were then capped and allowed to incubate for two hours in a water bath held between 40 and 48 degrees C. Following incubation, the specimens, together with fresh 1 c.c. samples of the same whole blood and serum, were precipitated with 1 c.c. 10 per cent sodium tungstate, followed by 8 c.c. $\frac{1}{12}$ normal sulfuric acid. After thorough stirring, especially with the incubated tubes, they were allowed to stand ten minutes, then centrifuged.

A 2 c.c. aliquot of the clear supernatant fluid was pipetted into tubes and diluted to 10 c.c. with distilled water. To each was added 4 c.c. 5 per cent sodium cyanide, followed by 1 c.c. arseno-phosphotungstic acid. The tubes were inverted once and placed immediately in a boiling water bath for three minutes, removed from the bath and allowed to stand about one minute at room temperature, one minute in cold water, and were read after a total of three minutes and within the next five. A 650 mμ filter was used, reading on a logarithmic scale. Too rapid cooling or delay in reading usually resulted in clouding.

*From the laboratory of the Maternity Hospital and the Department of Biochemistry, Western Reserve University School of Medicine.

Received for publication, Sept. 21, 1942.

The 5 per cent sodium cyanide was made up in water containing 1 c.c. concentrated ammonium hydroxide per 500 c.c. The arseno-phosphotungstic acid was prepared by dissolving 100 Gm. sodium tungstate in 600 c.c. water, adding 50 Gm. pure arsenic pentoxide, 25 c.c. syrupy phosphoric acid (85 per cent H_3PO_4), and 20 c.c. hydrochloric acid in a liter flask. The mixture was boiled 20 minutes, cooled, and diluted to 1 L. This reagent keeps indefinitely.

The standard was prepared as recommended by Benedict and Hitchcock,[7] and contained 0.2 mg. per 1 c.c. This keeps at room temperature about one month if tightly stoppered and only opened infrequently. For use, 1 c.c. was diluted to 100 c.c. Samples of 1, 2, 4, and 5 c.c. of this diluted standard, corresponding to 1, 2, 4, and 5 mg. per 100 c.c. of blood, were used to establish a curve, plotting the electrophotometer readings against the concentrations. This curve was found to alter slightly with successive daily readings, and it was found necessary to repeat it every third day, using freshly diluted standard. The points on these curves invariably plotted in a straight line, the alteration being due to change in the 5 per cent sodium cyanide solution. Neither using different brand preparations of cyanide nor the addition of urea prevented this alteration, which was quite probably due to change in the ammonia concentration.

RESULTS

Employing the method as outlined, we examined fifty-one male medical students, twenty-two normal young women, and thirty-seven normal women in the last trimester of pregnancy. A complete summary of the findings on the male group is given in Table I. The means for the whole blood and serum uric

TABLE I

URIC ACID DETERMINATIONS ON 51 HEALTHY YOUNG MALES

(Values in Milligrams per 100 c.c. Blood or Serum)

	MEAN	S. D.	RANGE	EXCEPTIONS
Whole blood	3.59	0.77	2.05- 5.13	2 low, 1 high
Whole blood plus uricase	1.67	0.51	0.65- 2.67	0 low, 2 high
True uric acid	1.92	0.58	0.76- 3.02	1 low, 1 high
Serum	4.30	0.92	2.46- 6.14	2 low, 0 high
Serum plus uricase	1.07	0.42	0.23- 1.91	0 low, 1 high
True uric acid	3.23	0.60	2.03- 4.43	2 low, 0 high
Hemoglobin	15.51	1.23	13.05-17.97	2 low, 0 high

The range is determined by adding and subtracting 2 times the standard deviation from the mean; theoretically it includes 95 per cent of all determinations.

Correlation of the direct uric acid values of the whole blood and serum is plus 0.857.

Correlation of the true uric acid values of the whole blood and serum is plus 0.89.

Correlation of the direct whole blood uric acid values and the hemoglobin is minus 0.139.

acid, each of which is well over four times the standard deviation (S. D.), are significant, although the values are somewhat closer than had been anticipated. Moreover 95 per cent of the determinations made fall within the range according to statistical theory. There is some question, however, as to the significance of the means of the whole blood with uricase, the true uric acid of the whole blood, and the serum plus uricase, which are only about three times the standard deviation. The hemoglobin values are definitely significant, as the mean is well over twelve times the standard deviation. In the indirect method the correlation

figure of plus 0.89 between the amount of true uric acid in the whole blood and the amount in the serum indicates a definite relationship between the two. There is likewise a relation between the uric acid of the whole blood and of the serum in the direct method, with a correlation figure of plus 0.857. On the other hand, there is no relation between the uric acid of the whole blood and the hemoglobin, with a correlation value of minus 0.139.

TABLE II

COMBINED URIC ACID FINDINGS ON 51 MALES AND 22 FEMALES

(Values in Milligrams per 100 c.c. Blood or Serum)

	MEAN	S. D.	RANGE	EXCEPTIONS
Whole blood	3.53	0.707	2.11-4.91	2 low, 1 high
True uric acid	1.77	0.565	0.64-2.90	0 low, 4 high
Serum	4.14	0.866	2.41-5.87	2 low, 0 high
Serum plus uricase	1.19	0.393		
True uric acid	2.95	0.734	1.48-4.42	1 low, 1 high

Correlation of direct serum uric acid and the serum plus uricase values is plus 0.333.
Correlation of direct whole blood and true uric acid values is plus 0.727.
Correlation of direct serum and true serum uric acid values is plus 0.951.

A very brief summary of the combined findings of the young men and women are given in Table II. These means, from three to five times their respective standard deviations, are all significant. The ranges, while somewhat more restricted than those for the men alone, have no more exceptions than were found in Table I.

The most interesting observation is the correlation found between the uric acid as determined in the whole blood and the true uric acid, plus 0.951. This would indicate that, although there seems to be no relation between the direct determinations of uric acid and the impurities, as for example, the correlation value of plus 0.333 between serum and serum plus uricase, there is a definite relation between the direct determinations and the true uric acid. One is therefore justified in using the direct method on either whole blood or serum, provided only that the results are compared with the normal range established by this method.

TABLE III

DETERMINATIONS ON 37 WOMEN IN THE LAST TRIMESTER OF PREGNANCY

(Values in Milligrams per 100 c.c.—Volumes in Per Cent)

	MEAN	S. D.	RANGE	EXCEPTIONS
Uric acid in whole blood	3.21	0.648	1.90- 4.50	1 low, 3 high
True uric acid	1.19	0.504	0.18- 2.20	1 low, 1 high
Uric acid in serum	3.59	0.94	1.71- 5.47	0 low, 3 high
True uric acid	2.24	0.761	0.72- 3.76	0 low, 2 high
Hemoglobin	10.53	1.28	7.97-13.09	0 low, 0 high
Red cell volume	32.60	3.946	24.70-40.50	0 low, 2 high

Correlation of direct uric acid values in the whole blood and the red cell volume is minus 0.109.
Correlation of the direct uric acid values in the serum and the red cell volume is minus 0.161.
Correlation of the direct and true uric acid values of the whole blood is plus 0.89.
Correlation of the direct and true uric acid values of the serum is plus 0.97.

Table III summarizes the findings on pregnant women in the last trimester. Here again the whole blood and serum uric acid means are four to five times

their respective standard deviations, and therefore significant. While those of the true uric acid by the indirect method are of less definite significance, their range includes the theoretical proportion of the determinations. Both the hemoglobin and red cell volume means are definitely significant. There is no correlation between the uric acid either of the whole blood or of the serum with the red cell volumes. There is, however, excellent correlation between the whole blood and true uric acid, and between the serum and true uric acid, with values of plus 0.89 and plus 0.97 respectively.

In view of these findings, particularly that of the apparent correlation between the whole blood and serum uric acids, it would appear that uric acid determinations on whole blood are fully justified. The complete lack of correlation between whole blood uric acid and either hemoglobin or red cell volume, and also the absence of correlation between the serum uric acid and the hemoglobin or cell volume confirms the belief that it is unnecessary to use serum for uric acid.

TABLE IV

URIC ACID DETERMINATIONS ON INDIVIDUAL PREGNANCY CASES
(Values in Milligrams per 100 c.c. Blood or Serum)

	DATE	DIRECT WHOLE BLOOD	TRUE WHOLE BLOOD	DIRECT SERUM	TRUE SERUM	
D. M.	4/22/42	6.75	3.35	9.30	6.60	Near term
	4/23/42	5.40	2.40	7.85	5.45	
	5/ 6/42	3.30	1.40	5.45	3.95	
W. S.	9/ 2/42	9.60	7.3			Aborted at about 8 weeks
	9/ 8/42	3.20	2.2			

Table IV is included to illustrate further the correlation between the direct determinations of uric acid in whole blood or serum and the pure uric acid values found by the uricase method, even when the uric acid retention is above normal. The first case, D. M., was a diabetic near term; the second, W. S., had suffered a spontaneous abortion at about eight weeks, due to an Rh reaction, with a resulting retention that raised her blood urea nitrogen to 115 mg. per 100 c.c. In both cases the ratio of the values obtained with Benedict's direct method to the true uric acid values during retention is proportional, within the limits of correlation, to the ratio of the same determinations in the normal range. This further justifies the employment of the direct method.

SUMMARY

The direct method of Benedict was found most suitable for determining uric acid with the photoelectric colorimeter.

Either whole blood or serum may be used since there is a direct correlation between the findings.

There is also excellent correlation between the direct whole blood or serum determinations and the true uric acid findings made with the aid of uricase.

Ranges have been established for uric acid by both the Benedict direct method and the same method, after correction with the aid of uricase, for both

whole blood and serum, in males, males and females, and in normal pregnant women.

QUANTITATIVE DETERMINATION OF BILE PIGMENT IN THE URINE*

A Comparative Study and Description of a Rapid, Direct, Photocolorimetric Method

Karl Singer, M.D., and Rosa Kubin, Ph.D., Boston, Mass.

DURING the last few years several methods for the quantitative determination of bile pigment in the urine have been published. Although such determinations may at present appear to be of but limited diagnostic value in the clinical study of liver diseases, they are of great importance for investigations of the hemoglobin and bile pigment metabolism in patients and experimental animals (renal biliary fistula dog[1]). Obviously, any quantitative determination of urinary bile pigment excretion should attempt to include all bile pigment compounds which could possibly be present. According to the view of Lemberg,[2] the primary bile pigment (not linked to globin) which develops in the course of hemoglobin catabolism, is not bilirubin but biliverdin (dehydrobilirubin). This substance, however, is immediately and completely reduced to bilirubin in the body, at least in man and dogs. In certain other species (frogs, birds) this reduction does not occur, and the color of the bile therefore is not brown but bluish green.[3] Under certain pathological conditions, e.g., in starvation (Thierfelder[4]), the reduction of biliverdin may also be incomplete and then the bile is composed of a mixture of both pigments. Furthermore, when bilirubin containing urine is exposed to light and air, a rapid, secondary reoxidation to biliverdin and sometimes to even higher oxidation products (choletelin) occurs. Thus, determinations of bilirubin only, are apt to give an inaccurate picture of bile pigment excretion.

At the present time the available quantitative methods for urinary bile pigments can be classified in two different ways. (1) according to the type of

*From the Department of Clinical Pathology, Middlesex University, Waltham, Mass.
Received for publication, Sept. 23, 1942.

chemical reaction used for the determination; (2) in regard to the preceding preparation of the urine for the performance of this chemical reaction, i. e., either separation of the bile pigments by precipitation, or direct determination in the urine without any preparation. As biliverdin cannot be diazotized, methods employing the van den Bergh reaction determine bilirubin only (Goodson and Sheard,[5] Scott,[6] Jendrassik and Czike,[7] and others[8]). If oxidation reagents are used, biliverdin besides bilirubin is included in the result (Hooper and Whipple,[9] Rous and McMaster,[10] and Knutti, Hawkins and Whipple[11 a, b]).

As the varying color of the natural urinary bile pigments (uroerythrin, urochrome, urobilin, etc.) interferes with the color obtained from the interaction between the bile pigments and the added reagents, most methods first separate the bile pigment compounds. Various precipitants are employed: calcium chloride (Hooper and Whipple[9]), barium salts (Scott[6]), trichloracetic acid (Kerpolla[12]). Such a precipitation is time consuming and increases considerably the inaccuracy inherent to any chemical performance. Recently Goodson and Sheard[5] found a way to avoid precipitation by excluding the disturbing natural pigments by means of an appropriate filter in the photoelectric colorimeter. This elegant method, therefore, permits a direct determination. Goodson and Sheard,[5] however, used the diazo reaction in their studies. Since we believe, for reasons which have already been broached, that oxidation methods are to be preferred in determining urinary bile pigments, we have worked out a direct photelometric method. This method is presented in this paper together with a comparative study of the other types of methods available for quantitative determination of urinary bile pigment compounds.

METHOD

Hammarsten's[13] reaction was used for the oxidation of the bile pigments. This reaction consists in the development of a persistent greenish-bluish color, when a mixture of hydrochloric and nitric acid in ethyl alcohol is added to fluids containing bilirubin or biliverdin. The reaction is quite analogous to the Gmelin test, but has the advantage that the oxidation remains arrested at a certain level and does not rapidly proceed further to colorless compounds, as is the case in the Gmelin test. This makes Hammarsten's[13] procedure suitable for colorimetric purposes.

Solutions Required.—(1) Hammarsten's reagent: the stock solution is prepared by mixing 19 parts of a 25 volume per cent hydrochloric acid with 1 part of a 25 volume per cent nitric acid. After twenty-four hours the stock solution is ready for use and then keeps indefinitely. For each test, 1 c.c. of the stock solution is diluted with 4 c.c. of absolute ethyl alcohol. (2) Blank solution: 7.5 c.c. of concentrated hydrochloric acid are diluted with water to make 1 liter.

Procedure.—The pH of the urine should first be tested with nitrazine paper. If the pH is higher than 6, a few drops of glacial acetic acid should be added to obtain an acid urine. Two test tubes or two graduated 10 c.c. cylinders are designated as "blank" and "test" respectively. Into each tube 1 to 2 c.c. of the centrifuged or filtered urine are then poured and 2 c.c. of 95 per cent alcohol are added, the contents are then well mixed by rotating the tubes. Then to the "blank" tube 2 c.c. of the blank reagent are added slowly, and to the "test" tube 2 c.c. of the diluted Hammarsten reagent. Both solutions, after

mixing again, are further diluted up to 10 c.c. by means of alcohol. The bluish-greenish color develops readily in the "test" tube and reaches its maximal intensity after two to five minutes. In the "blank," cloudiness caused by the precipitation of salts by the alcohol, may sometimes be noticeable. In this case the solution is filtered until completely clear. Occasionally it may be difficult to obtain a clear filtrate, in which case the "blank" may be prepared with distilled water instead of alcohol, without influencing the colorimetric evaluation.

Fisher's photoelectrocolorimeter (microset) was available in our laboratory. The red filter (650 $m\mu$) was used. Although no special spectrophotometric studies could be performed, our results confirm the findings of Goodson and Sheard[5] that the disturbing influence of the various urinary pigments can be eliminated by the use of an appropriate filter if the diluted, untreated and acidified urine is employed as a standard for the photelometric comparison. The "zero-point" was determined with ethyl alcohol. Then the "blank" was read and the figure obtained was subtracted from the figure of the "test" solution.

Standardization.—From a stock solution of 20 mg. of bilirubin (Pfannenstiel) in 100 c.c. chloroform, convenient series dilutions were prepared and the oxidation tests performed. The photelometric readings were plotted in a calibration curve on semilogarithmic paper. Like the "diazoreaction" curve, the "oxidationreaction" curve obtained, is not a strictly straight line. The most reliable readings are obtained for a concentration of 0.15 to 0.4 mg. bile pigment per c.c. of urine. If the concentration in a urinary sample should be found out of this range, adaptation to the test by adequate increase or decrease of the amount of urine used is recommended.

COMPARATIVE STUDY

Urine samples from four dogs with renal biliary fistulas* and from four patients with extrahepatic obstructive jaundice were used for the comparison of the above described method with three other types of determination of biliary pigment. These other methods were (1) the direct diazo method of Goodson and Sheard,[5] in which caffeine sodium benzoate is employed as an accelerator in the development of the color reaction, (2) the method of Whipple and his associates,[11] employing calcium chloride for precipitation and nitric acid for oxidation, (3) Scott's[6] method using barium salts for precipitation and the diazo reaction for the determination. The results obtained with the four methods can be seen in Table I; each value therein is the arithmetic average of two parallel determinations.

In most of the experiments the highest values found were with the new direct oxidation method. In order to have a basis for a comparison of the different methods the results of the direct oxidation are assumed to equal 100 per cent and the other values are computed on this assumption (Table II).

DISCUSSION

1. *Comparison of the Two Direct Methods.*—(New oxidation method and diazo method of Goodson and Sheard,[5] Columns 3 and 4 of Tables I and II).

*We want to express our gratitude to Dr. Louis Bergmann and Dr. Leo Weisz for their cooperation in performing the operations.

Performance of the direct oxidation test requires only one-third of the time needed for the diazo test. Both methods give almost identical results with the urines of jaundiced patients (No. 11 to 14). In these experiments only freshly voided specimens were used. With fresh dog urine also, the same results were obtained (No. 8). In all the other animal experiments a twenty-four-hour urine was collected in a brown flask containing chloroform as a preservative,[11] the animal being in the metabolic cage. The diazo values, measuring bilirubin only, were always lower in these specimens, sometimes quite considerably. This is best explained as a result of the secondary reoxidation of the excreted bilirubin.

That bilirubin, when exposed to light and air, may rather rapidly disappear from a urinary specimen, has been repeatedly observed. (Rabinowitch,[14] Sivo and Forrai,[15] Scott[6]). Other factors, like temperature and ultraviolet rays, may also be of contributing importance (Peterman and Cooley[16]). The disappearance of bilirubin is caused mainly by reoxidation to compounds no longer giving the diazo reaction. The higher values of the oxidation method demonstrate clearly the superiority of this type of determination. However, the lower values with the diazo test may sometimes also be due to other causes. During the course of our experiments with the renal biliary fistula dogs almost daily determinations of the bile pigment output were performed using the method of Goodson and Sheard.[5] Immediately after operation the proper reddish-purplish color of diazobilirubin was obtained; later on, however, varying from a few days to a few weeks postoperatively, the diazoreagent, when added to the urine, produced only a brown or even a green color, unrelated to the pH of the specimen. Simultaneously with this phenomenon the urine began to contain great amounts of indican (highly positive Jolles and Obermeyer tests). That indican or related substances may interfere with the van den Bergh reaction in the plasma has been noted by previous investigators. Andrewes,[17] Harrison and Bromfield,[18] and also Becher[19] mention particularly the "buff or brown diazoreaction" in uremia where indican accumulates in the blood. The cause of the considerable indicanuria in our renal biliary fistula dogs was presumably the complete absence of bile from the intestine; bile was not administered to these animals because it would have interfered with a simultaneous investigation using these same dogs.

Two further questions deserve a brief discussion. (1) Does the Hammarsten reaction used in the direct oxidation test determine bile pigment compounds only? Hans Fischer and Adler[20] studied the different phases of the similar Gmelin test and found that other substances like malachite green, crystal violet, dimethylaminoparabenzol, etc., may give similar color compounds. All these substances are, however, unlikely to be present in any pathological urine. Indican, according to Naumann,[21] gives a very slowly developing bluish color with trichloracetic acid and Ferric chloride (Fouchet's reagent). We found in numerous urines not containing any bile pigment that indican, normal urinary pigments, and also stercobilinogen, prepared from feces, if added to the urine, did not give a positive Hammarsten test. Indican alone gives a brown color with the diazo reagent. (2) The second problem is whether the direct oxidation method determines all the excreted bile pigments or whether a loss occurs due to superoxidation to choletelin or colorless compounds. In order to answer this question dog

bile was taken from the gall bladder and the bile pigment content was immediately determined with both direct methods. Then the bile was protected against light and air by placing it in a dark bottle and adding mineral oil. In the fresh dog bile no biliverdin was present, as can be seen from the identical values with both the diazo and the oxidation tests (Table III). The values of the protected and also of the unprotected bile samples were then compared after twenty-four hours. Similar experiments were performed with urines. The results are compiled in Table IV.

TABLE IV

QUANTITATIVE RECOVERY OF BILIRUBIN ADDED TO URINE

SAMPLE NO.	MILLIGRAMS OF BILIRUBIN PER C.C.				PERCENTAGE RECOVERED
	IN URINE	IN BILIRUBIN SOLUTION	IN URINE PLUS BILIRUBIN		
			FOUND	ANTICIPATED	
1	none	0.20	0.190	0.200	95.0
2	none	0.26	0.250	0.260	96.1
3	none	0.37	0.380	0.370	102.7
4	none	0.55	0.560	0.550	101.8
5	none	0.89	0.810	0.890	91.0
6	0.135	0.17	0.273	0.305	89.5
7	0.140	0.17	0.279	0.310	90.0
8	0.320	0.17	0.510	0.490	104.1
9	0.137	0.30	0.430	0.437	98.4
10	0.770	0.21	0.950	0.980	96.9

Average recovery 96.6 per cent; range 89.5 to 104.1 per cent.

With one exception (No. 6, Table III) the value obtained with the oxidation test remained constant in the protected sample whereas all the other values decreased considerably. From these results it may be concluded that the oxidation test in samples adequately protected against superoxidation gives probably the most reliable picture of actual bile pigment excretion, although the possibility of a loss caused by superoxidation must always be kept in mind when balance studies of the pigment metabolism are performed.

2. *Comparison of the Two Oxidation Methods.*—(New direct method and precipitation method of Whipple and associates,[11] Columns 3 and 5, Tables I and II). The values estimated with the precipitation method showed deviations from those with the direct test covering a range from –28.4 per cent to +15.0 per cent, with an average deviation of –13.4 per cent. The standard deviation σ is 18.5 per cent. Most of the values with the precipitation method are lower than those with the simpler direct test. This is partly due to the loss to be expected from the more complicated chemical procedure, and perhaps partly caused by the difficulties in achieving the correct degree of oxidation of the bile pigments. The method of Whipple and his associates[11] requires an experienced worker as the amount of their oxidation reagent added to the urine

must be carefully adapted to the constantly varying concentration of pigment present, which factor may result in an insufficient or too efficient oxidation of the bile pigment compounds. These dangers are eliminated in the direct photelometric test. Peterman and Cooley[16] studied the various conditions of significance in obtaining maximal oxidation of bile pigments and recommended hydrogen peroxide as the most suitable oxidation reagent. Malloy and Evelyn,[22] following their suggestion, described a photo-electric method using hydrogen peroxide for determination of bile pigment in bile, feces and meconium. In our experience oxidation with hydrogen peroxide does not give satisfactory results with urinary bile pigment. Peterman and Cooley,[16] and Malloy and Evelyn[22] also expressed the opinion that the green color of fluids containing various bile pigments is not due to the presence of biliverdin. According to these authors biliverdin does not exist as a chemical entity but represents only a mixture of unoxidized yellow bilirubin and blue bilicyanin. This is in sharp contradiction to Lemberg,[2, 3] who defines biliverdin as a bile pigment compound having two hydrogen atoms less than bilirubin and an open α but an intact γ methene bridge. Both statements are most likely only at variance as far as the terminology is concerned. Biliverdin is a definite chemical substance but the green color of fluids containing bile pigment may also sometimes be caused by the presence of a mixture of unoxidized and oxidized pigments. In order to demonstrate that the direct oxidation test which yields a bluish-greenish color, does not leave any bilirubin undetermined, quantitative recovery experiments of bilirubin added to urinary samples were performed. The bilirubin was dissolved in chloroform and then added to urines with and without natural bile pigment. When performing the test, no technical difficulties were encountered, as chloroform in small amounts is readily soluble in alcohol, which is the main fluid medium of the test.

The recovery of bilirubin is as complete as can be expected from such an experiment. The range of the results was 89.5 per cent to 104.1 per cent and the average recovery 96.6 per cent. These values are almost identical with those found by Goodson and Sheard[5] in similar recovery experiments with their direct diazo method.

3. *Comparison of the Two Diazo Methods.*—(Direct method of Goodson and Sheard[5] and precipitation method of Scott,[6] Columns 4 and 6 of Tables I and II). If bilirubin only is to be determined in the urine, the direct oxidation method is doubtless the method of choice. The direct method is not only simpler to perform, but combines, as can be seen from the tables, this advantage with a much higher degree of accuracy.

CONCLUSIONS AND SUMMARY

1. Quantitative determination of urinary bile pigment excretion should attempt to comprise all bile pigment compounds which could possibly be present. Methods using the diazo reaction determine bilirubin only. Therefore oxidation methods which include also bile pigments other than bilirubin are to be preferred.

2. A direct, rapid, quantitative, photo-electric method, using Hammarsten's oxidation reaction, is described. By means of an appropriate filter and by

employing the diluted acidified but untreated urine as a standard, the otherwise necessary preliminary precipitation of the bile pigments can be eliminated.

3. A comparative study of this method with three other types of quantitative determination of urinary bile pigments is reported. The methods used in this comparison were (1) the direct diazo method of Goodson and Sheard, (2) the precipitation and oxidation method of Whipple and associates, (3) the precipitation and diazo method of Scott. Urines of renal biliary fistula dogs as well as of jaundiced patients were used in this study.

4. By means of the oxidation test and by an adequate protection against superoxidation, a reliable quantitative determination of the bile pigments excreted in the urine in twenty-four hours can be obtained, although the actually excreted amounts of bilirubin may decrease considerably in the collection period.

BOOK NOTICES

Hemorrhagic Diseases*

NYGAARD'S *Hemorrhagic Diseases* is a volume on blood coagulation and its mechanism, with a special discussion on the photoelectric method of determination of blood fibrin, also of the several hemorrhagic diseases. There is a discussion of vitamin K, but not of heparin.

Synopsis of Materia Medica, Toxicology and Pharmacology†

THE appearance of a second edition two years after the first speaks well for the popularity of Davison's *Synopsis of Materia Medica, Toxicology and Pharmacology.* It is rather difficult to visualize a 700 page book being a synopsis, but when compared with larger texts on the subject it emerges as truly synoptic in character. This brings us to the realization of the tremendous increase in our knowledge of the action of drugs and in the number of new drugs, in the past several years.

The volume is primarily clinical and serves as a ready reference manual.

Pathology of Trauma‡

THE pathology of trauma is a subject about which little is known to the average practitioner and medical student. Yet trauma ranks high in the list of causes of mortality and morbidity. In his book Dr. Moritz not only describes the pathology of trauma but also explains most lucidly why specific injuries take the form which they do. He calls upon an engineer's knowledge of forces, stresses, and vectors to make this clear to the reader. The book is not written from the point of view of the traumatic surgeon but from that of the pathologist and medical examiner. Consequently, it will be most valuable to persons in those fields. However, the background of knowledge which Dr. Moritz has drawn upon for the presentation of his subject is so broad that his book has a natural appeal to all physicians and students. The greater part of the book is devoted to a consideration of mechanical injuries to the various systems of the body, and emphasis is placed on the question of the predisposition of trauma to disease. This is not only a clinical problem but a most important medico-legal one, and in each instance Dr. Moritz reviews completely the evidence for and against trauma as an etiologic factor in disease.

Intelligent treatment of wounds demands a thorough knowledge of not only the anatomy but the pathology involved. The great demand today for young doctors who are trained to practice traumatic surgery on the battlefields makes it particularly fortunate that Dr. Moritz' book has appeared at this time. It is profusely illustrated, and will be a valuable teaching adjunct for those doctors preparing themselves for military duty.

Mosby Company, St. Louis, 1942.

‡Pathology of Trauma. By Alan Richards Moritz, M.D. Cloth, 386 pages, with 117 illustrations, $6.00. Lea and Febiger, Philadelphia, 1942.

A Handbook of Allergy*

BLANTON'S *Handbook of Allergy* should fulfill well the purpose for which it is primarily intended. It is a synopsis type work for use by the undergraduate student, to be supplemented by personal instruction. It should also serve as a handy orientation volume for graduates who wish to become acquainted with the general subject of allergy. The discussion of treatment, both specific and symptomatic, is too abbreviated for the volume to serve adequately as a therapeutic reference aid. It is hoped that in the next edition treatment will receive more detailed discussion. When used as an undergraduate text, this becomes less of a problem since the student gains his therapeutic experience in the ward and clinic.

Directory of Medical Specialists†

THE second edition of the *Directory of Medical Specialists Certified by American Boards* is much larger than the first. A change in the page headings makes it a much more convenient reference volume. As previously, the specialties are arranged in alphabetical order. In the first edition page headings designated only the specialties. In the second edition the specialty appears on the left-hand page with the States on the right-hand and the cities scattered through the pages. This is a valuable reference volume.

Standard Nomenclature of Disease and Standard Nomenclature of Operations‡

THE *Standard Nomenclature of Disease* is now in its third edition. Many editions have been made, based primarily on the National Conference of Medical Nomenclature held under the auspices of The American Medical Association in 1940. For the first time there is also included a standard nomenclature of operations. Both sections are well indexed. Key numbers for all diseases and operations are arranged according to the punch card system so that with proper equipment any group or groups of diseases or operations may be sorted out with little expenditure of time.

The volume, published by The American Medical Association, will be especially valuable for teaching and research institutions, clinics, libraries, and statisticians.

Electrophoresis of Proteins§

ORIGINALLY a highly complicated phase of physical chemistry, electrophoresis has now entered much broader fields as an implement of investigation and has even found uses in clinical medicine. Most of us know it only by name but many are coming to realize that a more intimate acquaintance will be needed, as electrophoretic methods come to be applied in our own fields of study.

These authors describe general principles and methods of application and follow with discussion of studies of serum and plasma proteins, antibodies, antigens, enzymes, hormones, and the surface study of cells. The authors themselves have contributed a very great deal to this knowledge. The volume is necessarily still highly technical but recommended as the best reference volume on the subject that is available.

Outline of Histology*

HOSKINS and Bevelander's *Outline of Histology* is a loose-leaf laboratory book printed by the new photolithograph process. There are two columns to a page, facilitating easy reading, and many splendid illustrations. There is also an abundance of blank pages for notes and drawings. The volume should find wide use in the histological laboratory.

Drug Products†

HERRICK'S volume on *Drug Products* is a four hundred odd page description and analysis of the Federal Food and Cosmetic Act, designed to assist the manufacturer, distributor, and packer of drug products. It provides adequate interpretation of this complicated statute.

Human Pathology‡

THE sixth edition of Karsner's *Pathology* scarcely needs an introduction. However, there have been many changes from previous editions, enough to require resetting of type. The author and publishers have thereby taken advantage of the opportunity to make two column pages which facilitates reading. It has been abundantly and beautifully illustrated with 460 illustrations in black and white and 24 in color.

To Our Readers

The exigencies of the war situation have made it necessary to comply with the order of the War Production Board to reduce the weight of paper previously used for the JOURNAL. While this change will not affect the printed page it will affect the quality of the halftone illustrations. We regret that we have no choice in the matter and would ask the forbearance of our readers. As soon as the restrictions are removed, we shall resume our practice of printing the JOURNAL on the previously employed heavier grade of paper.

THE C. V. MOSBY CO., Publishers.

CLINICAL AND EXPERIMENTAL

THE DISTRIBUTION AND POLLINATION TIMES OF THE IMPORTANT HAY FEVER-PRODUCING PLANTS IN THE UNITED STATES*

Philip M. Gottlieb, M.D., and Erich Urbach, M.D., Philadelphia, Pa.

It is axiomatic that the precise etiologic diagnosis of hay fever requires a knowledge of the pollens to which the patient is exposed; in other words, a knowledge of the identity of those plants in the patient's vicinity which are capable of causing pollinosis, their relative prevalence, the average onset and termination of their pollinating seasons, and their pollen-producing capacity. Such information for each locality is essential in correlating the patient's symptoms with the presence of his allergens, in selecting the appropriate pollens with which to perform tests, in evaluating cases clinically diagnosed as hay fever but failing to react to tests, and in choosing the proper extracts for treatment. For practical application, information about the facts mentioned is of greater importance than the variations in the quantity of atmospheric pollen grains from day to day within the season.

Few physicians, of course, have the time, the requisite botantical training, or the facilities for carrying out pollen counts or field surveys. Hence, it is necessary to rely upon pollination studies previously completed in the same, or some comparable, locale. Although the seasons vary somewhat from year to year, depending on a number of meteorologic conditions (see below), they are usually sufficiently constant for the experience of previous years to be applied clinically.

*From the Allergy Service of the Jewish Hospital, Philadelphia.
Received for publication, Sept. 28, 1942.

There undoubtedly exists a great deal of unpublished data in this field. Much of it is in the hands of allergists located throughout the country, and a commendable effort has recently* been made by the Committee on a Pollen Survey of the Society for the Study of Asthma and Allied Conditions,[27] to tap this rich source of material. This investigation has not yet reached the point where it is useful to the practicing physician.

In addition, scattered throughout the medical literature are a large number of carefully performed investigations which, *in toto*, nearly blanket the United States. These, to be sure, differ widely in scope and technique, some including only a single species or one related group of plants and some reporting findings regarding only a portion of the hay fever season. Most pertain to one locale only, others cover extensive regions of the country, and still others are national or nearly national in extent. Many are based on atmospheric pollen counts by gravity or other methods, some are the result of botanical surveys, a few combine these two approaches, and still fewer correlate these findings with clinical observations. Deficiencies encountered in various articles

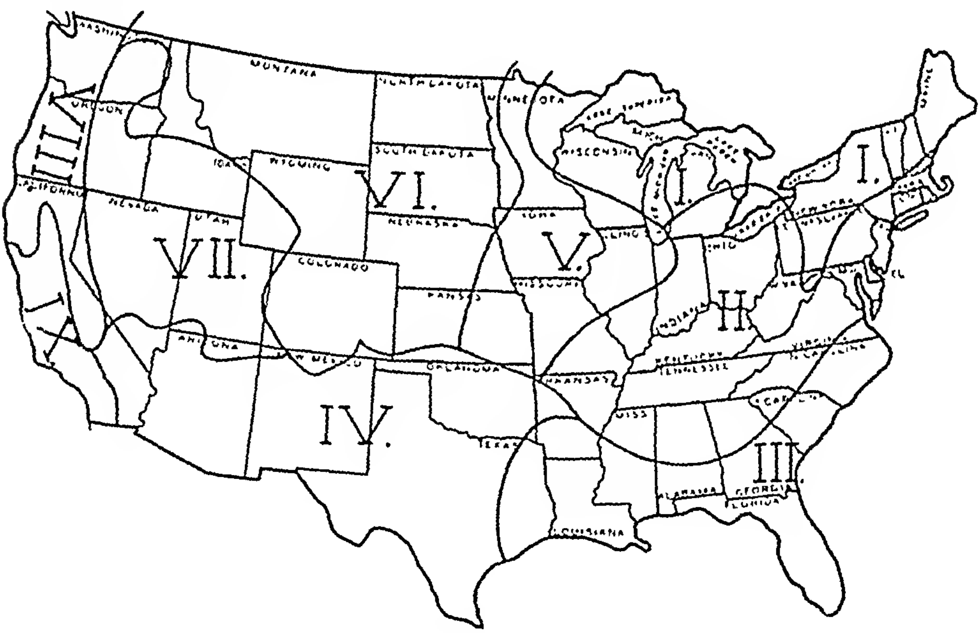

Fig. 1.—Division of the United States into nine pollination zones.

include omission of the duration of pollination and less frequently of its exact onset, grouping of several species into rough "seasons" rather than giving the separate dates, and inadequate identification of plants by ambiguous common names. Many fail to state the relative importance of each plant, or where given, to mention whether it is based on pollen counts, prevalence, abundance of pollen production, or the frequency of positive skin reactions. A common failing is the assumption, unsupported by actual determinations or any apparent scientific evidence, that the findings in a given city are characteristic of a whole state or even larger area, such as New England, the Middle Atlantic States, or the South.

*At the time this paper was undertaken and started, no such study had been begun.

Despite all these shortcomings, which, of course, by no means apply to all the reports, a great deal of useful information can be gained. And inasmuch as the data for one community can properly be considered to hold for at least a limited portion of the surrounding territory, all these observations can be compared and combined to give a representative, over-all picture of the pollen situation in the United States.

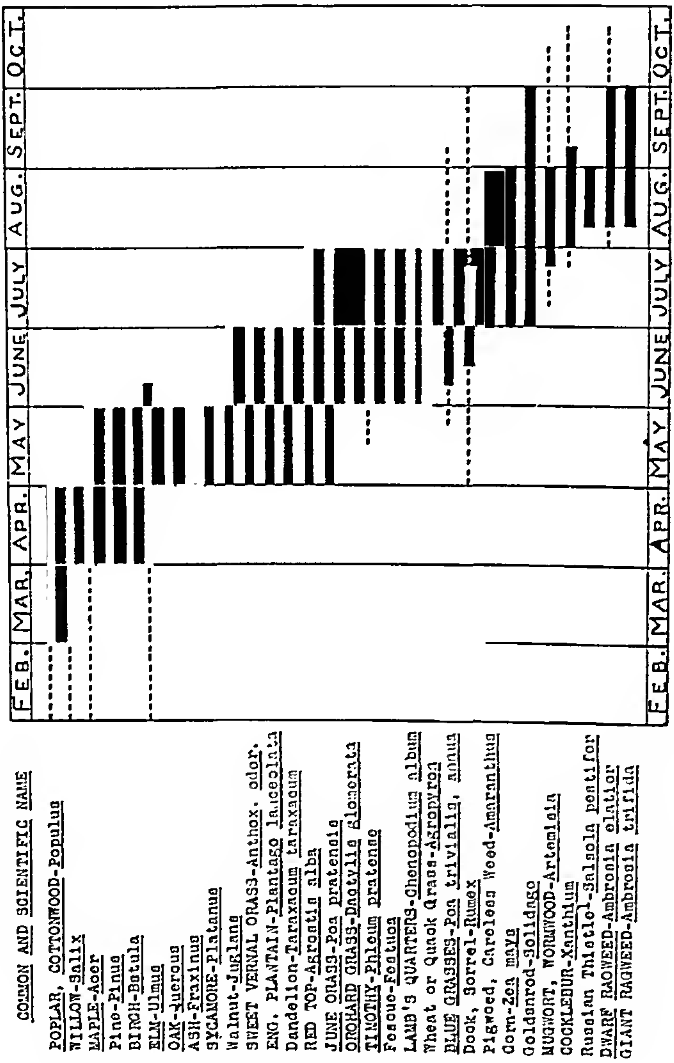

Fig. 2.—Pollination calendar for Zone I. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, Occurs in western portion of the zone only.

It is a botanical truth that probably no two species of plants precisely correspond in their distribution, range, or region of maximum growth.[1] Moreover, depending on the nature of the soil, the elevation, and a multitude of meteorologic factors, the dates of onset and cessation of pollination vary from place to place in the same area. Hopkins[2] has pointed out that, other conditions being equal, the variation in time of occurrence in temperate North America is at a general average rate of four days to each 1 degree of latitude, 5 degrees of longitude, and 400 feet of altitude, later northward, eastward, and upward

in spring and early summer, and the reverse in late summer and autumn. The average advance of the season per day is seventeen miles northward, sixty-two miles eastward, and 100 feet upward.

Nevertheless, for practical and clinical purposes, rather large districts can be considered to contain a certain type of flora with pollination seasons which, with some variation, are by and large uniform for that area. This is all the

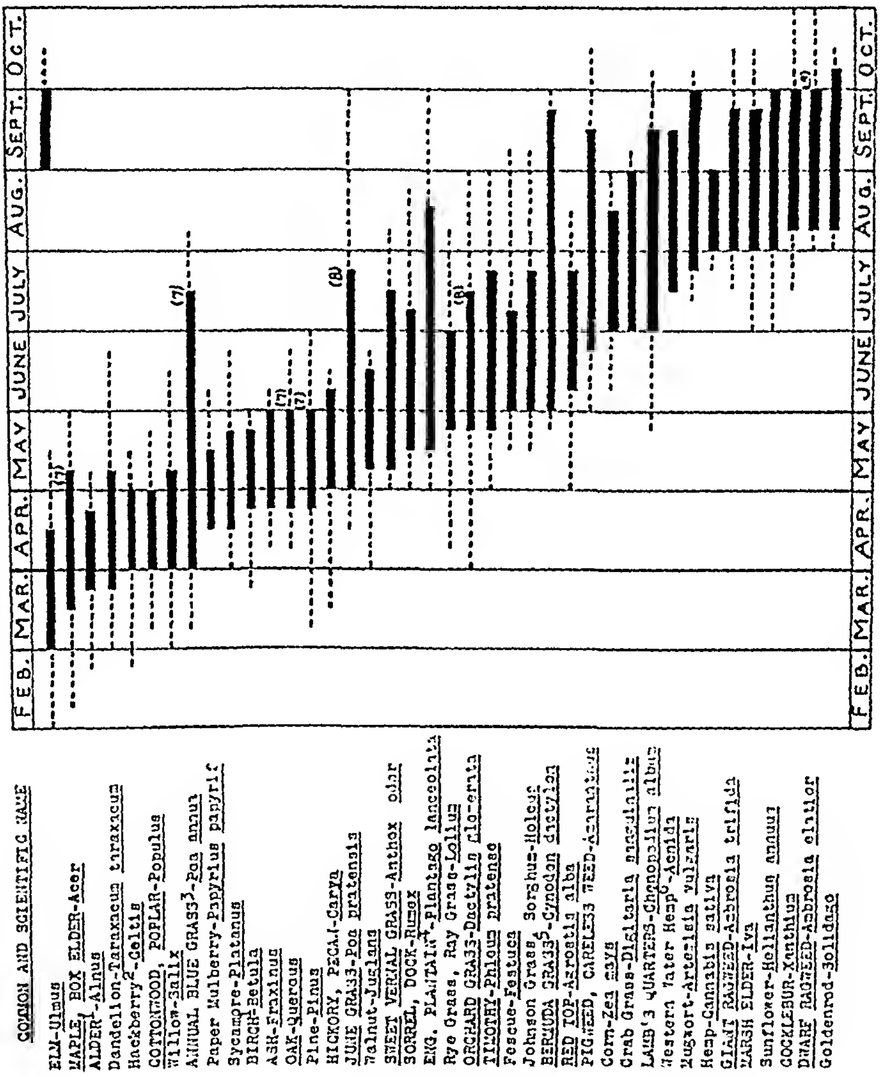

Fig. 3.—Pollination calendar for Zone II. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, Much less common in southern portion of zone; *2*, less common in northern portion; *3*, also *Poa compressa* ((Canadian blue grass) in northern portion; *4*, also *Plantago major* (common plantain), but less common; *5*, occurs in southern portion only; *6*, occurs in western portion only; *7*, pollinates one month earlier in southern portion; *8*, sometimes pollinates in January or February in southern portion; *9*, pollination commences somewhat later in southern portion.

more true in that the important hay fever-causing pollens can be carried by the wind for considerable distances, such atmospheric pollution tending to minimize the influence of local differences in plant life. It has been customary to divide the country into districts according to state boundaries or the usual geographico-economic units. A moment's thought will show that this cannot be correct for the present instance, since neither the plants themselves nor their air-borne pollens are any respectors of state borders. Even where states are bounded by rivers, the same flora is practically always established on both

banks. Hence, we have more logically resorted to the botanical-vegetational areas painstakingly delineated by Livingston and Shreve.[1] It was found necessary to modify their map to accord with more recent publications and with the

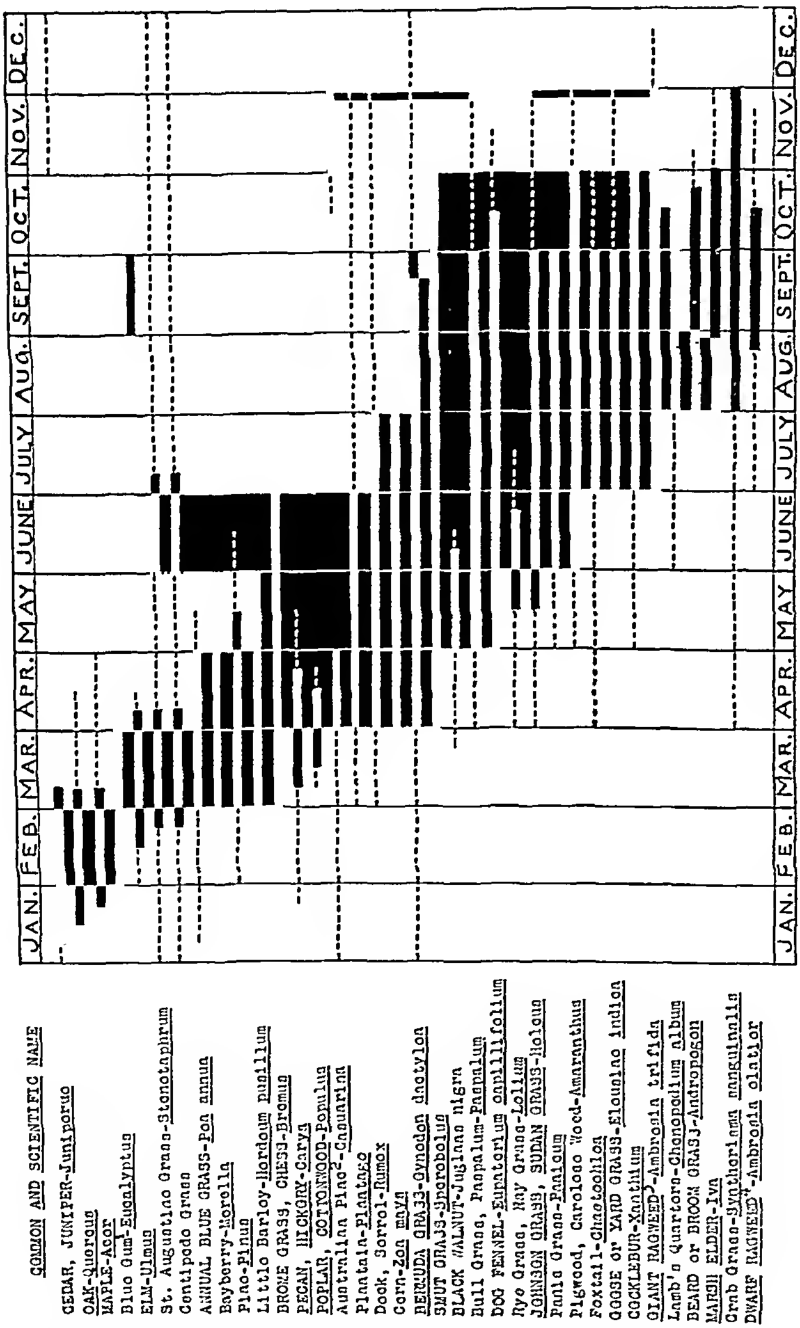

Fig. 4.—Pollination calendar for Zone III. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, Occurs in Florida only; *2*, occurs in southern Florida only; *3*, occurs chiefly in western portion—none in Florida; *4*, none in eastern Florida.

fact that we are solely concerned with plants capable of producing hay fever rather than with all the flora. Fig. 1 presents a division of the United States into nine zones according to these principles.

The literature yielded 166 articles containing usable information. Of these, forty-two covered the entire country, or at least large areas, as regards one or more species, and these are given first in the references. Parenthetically, it may

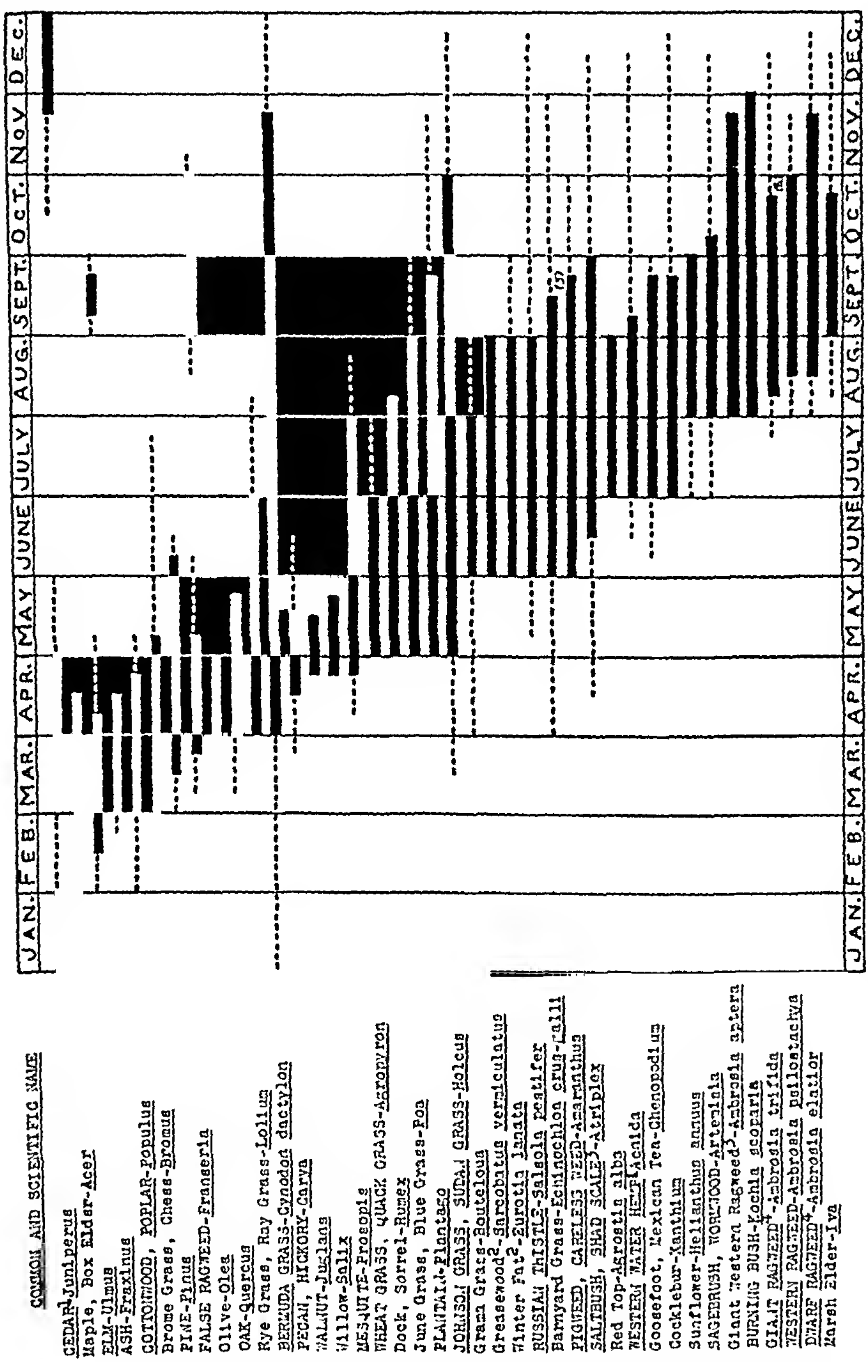

FIG. 5.—Pollination calendar for Zone IV. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. 1, Less common in western portion; 2, occurs in western portion only; 3, less common in eastern portion; 4, none in western portion; 5, pollinates perennially in protected areas; 6, pollinates earlier in extreme western Texas.

be noted that in six of them attention was confined to the West;[4, 20, 31, 36-38] in four, to the South;[8, 16, 29, 45] in four, to the Midwest;[7, 9, 22, 23] and in three, to New England and the Middle Atlantic States.[26, 39, 40] The remainder of the

articles are based on local studies or concern at most a state and are so listed. (In a few instances, portions of adjoining states were given consideration. These are entered only under the state primarily represented.) The bibliography also contains the references for Canada and Alaska.

By combining and, so to speak, "averaging" for each zone, the score or more surveys done in separate localities by various methods in different years, it is felt that a comprehensive view is obtained, which is, in some respects, possibly more accurate than the original studies themselves. The results of this method are given in Figs. 2 to 10, which constitute a pollination calendar for each of the nine zones.

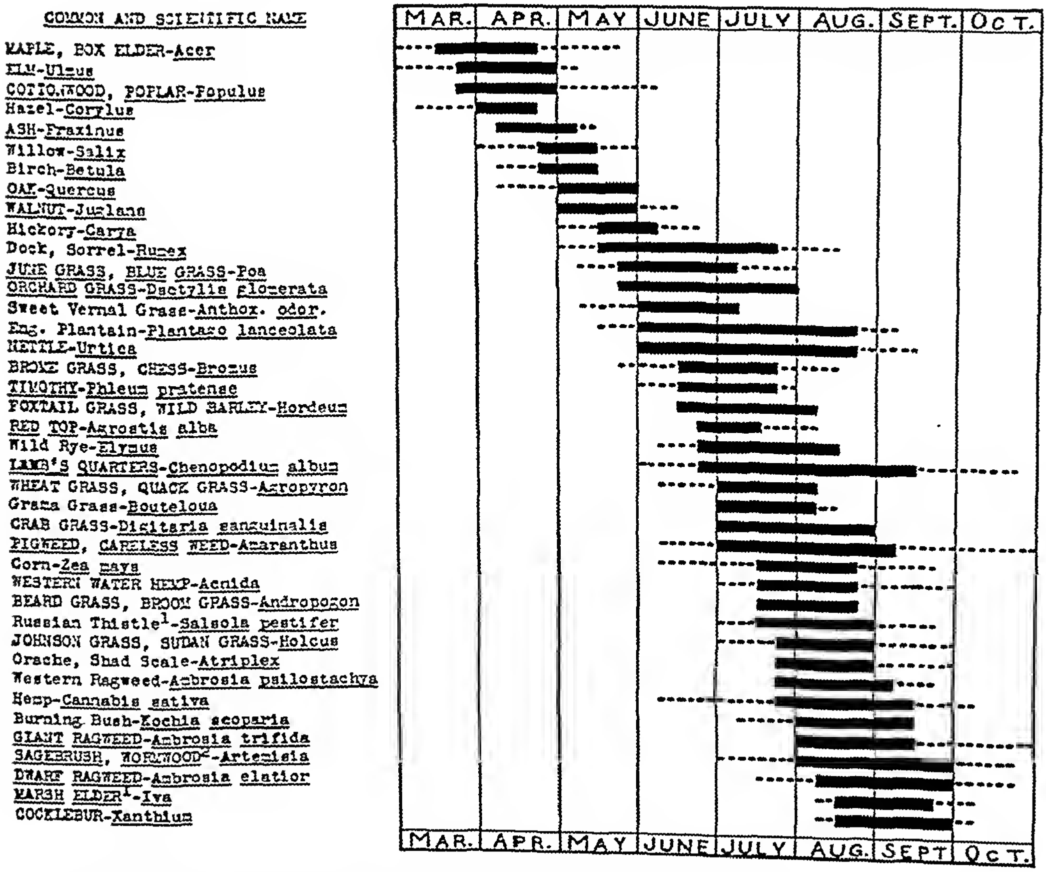

Fig. 6.—Pollination calendar for Zone V. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, None in Milwaukee, Wis.; *2*, very little in Omaha, Neb., and Milwaukee, Wis.

It must not be thought that all the plants mentioned in the literature are included in the figures. Only those of considerable importance were selected. As a matter of fact, references to nearly 300 species of weeds alone are to be found, plus hundreds of grasses and trees. The main pollination times are given in a heavy, unbroken line. This tends, in most instances, to be somewhat longer than the actual season at any one place in any one year because of the totaling of the commoner annual deviations, the combination of observations

from widely separated localities, climatic variations, differences in the time of planting of cultivated species, and other factors. This is especially true of the spring and early summer seasons rather than of late summer and fall.

It should also be pointed out that many plants pollinate sporadically both before and after the principal season, that local circumstances may influence the dates over a limited area, and that unusual weather conditions may correspondingly accelerate or delay pollination. All this is signified in the calendars by

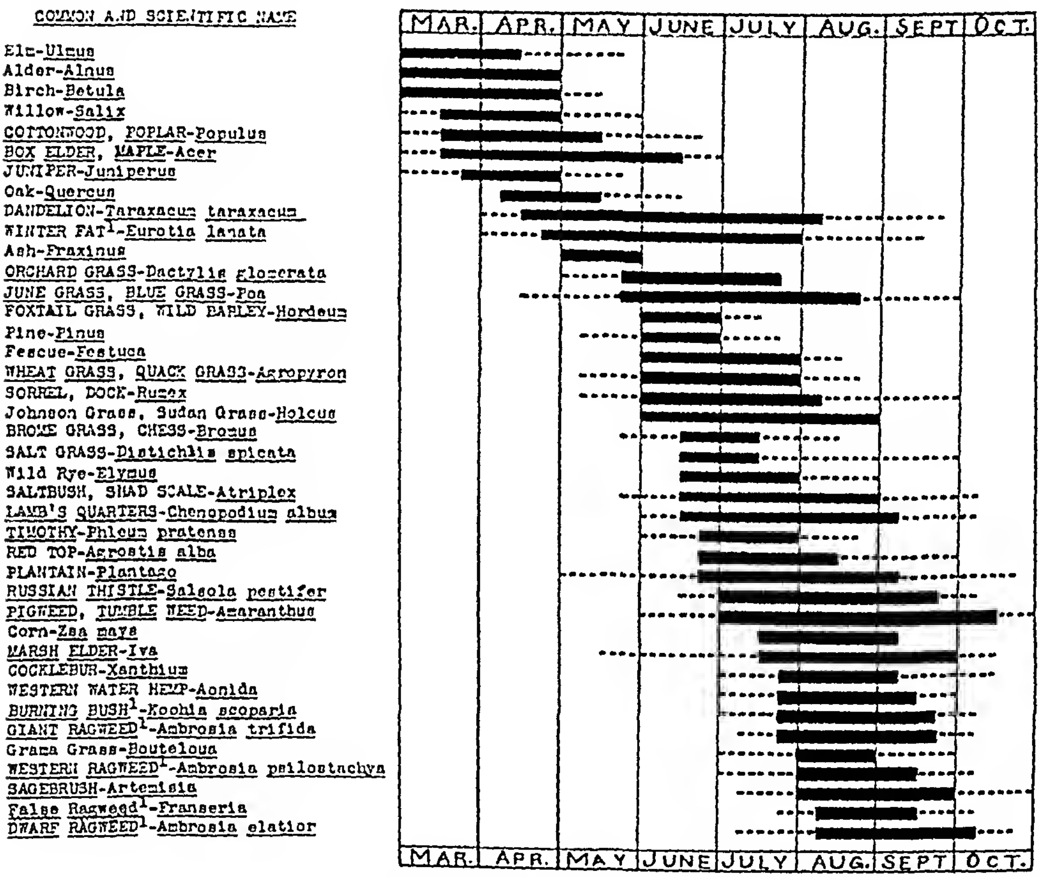

Fig. 7.—Pollination calendar for Zone VI. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, None in western Colorado, western Montana, or northern Idaho.

the finer, interrupted lines. Finally, the various trees, grasses, and weeds have been graded, according to their frequency and importance, into three groups: the major causes of hay fever, those of secondary significance, and those of lesser consequence. This, likewise, is indicated in the figures. Needless to say, other plants can, less often, be responsible for occasional cases of pollinosis, either as a result of unusual exposure or of extraordinary weather conditions. For localities near the boundary of a zone, it is suggested that the calendar for the adjacent zone also be consulted.

Naturally, certain sources of error are inherent in pollen surveys, whether by atmospheric count or botanical observation, and apply equally to this study, in so far as it is employed in any one locale.

In the first place, the beginning as well as the end of the pollination period depends, from year to year, on meteorologic factors, particularly the range of temperature, the percentage of sunshine, and the amount of precipitation. Thus, an especially warm spring and summer with heavy rainfall will appreciably advance the date of the first blooming, whereas a cold and dry preseason will delay it. The pollen calendar cannot do more than give the average dates.

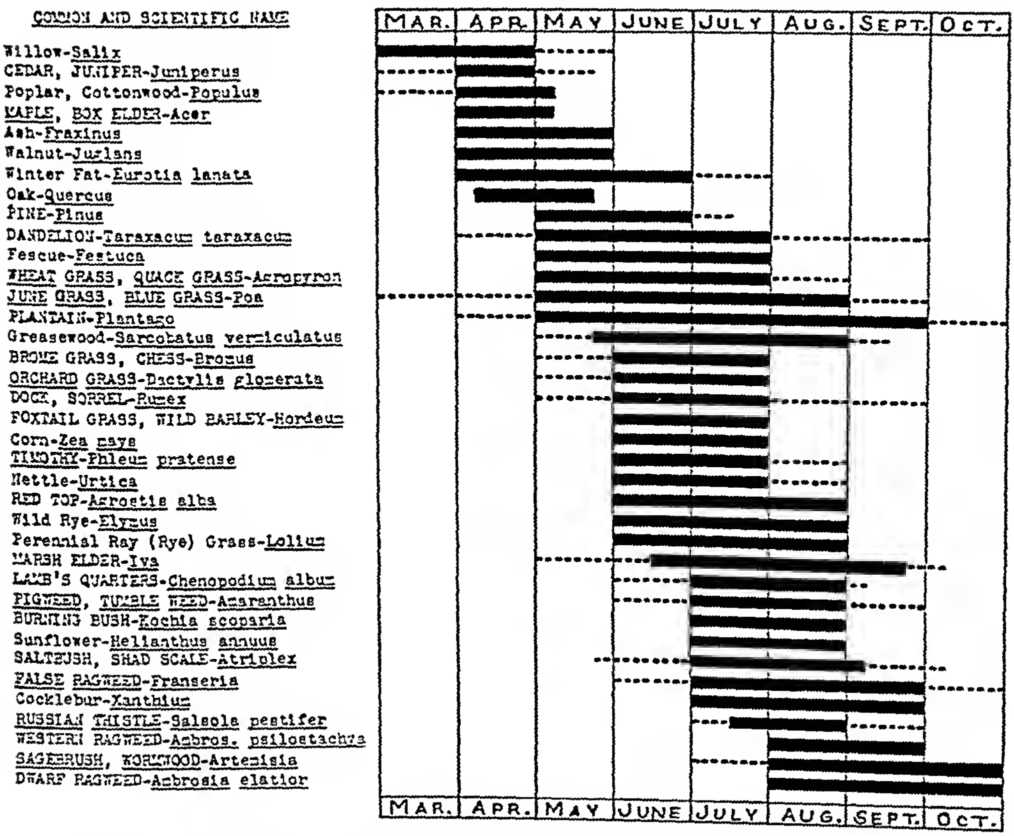

Fig. 8.—Pollination calendar for Zone VII. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively.

Fig. 11 shows how, under certain circumstances, the flowering can be hastened or retarded as much as two to four weeks. It will be seen that the onset of pollination of orchard grass (*Dactylis glomerata*) was found to vary in six consecutive years in one place from May 2 to May 29.

In the second place, extraordinary weather conditions can cause pollens which, under normal circumstances, are relatively unimportant in a given area to become major factors quite suddenly. Thus Feinberg and Durham[97] reported that in the Chicago area in 1934, unlike other years, the pollens from certain trees and from certain chenopodiales (for example, Russian thistle) were the principal allergizing agents. Duke[120] made the opposite observation that pollens which ordinarily were abundant in Kansas City, Mo., were either absent or nearly so in a season with unusual weather conditions.

Furthermore, in isolated cases, due primarily to uncommon conditions of exposure, individuals may be allergized by the pollen of trees, flowers, and

bushes which only very rarely cause hay fever. For example, Dutton[149] and Phillips[55] showed that in the fields near El Paso, Texas, and Phoenix, Ariz., respectively, where the common sugar beet (*Beta vulgaris*), a member of the family Chenopodiaceae, is intensively cultivated, some cases of hay fever are due to its pollen, which is shed from early May to mid-June. Present plans to augment greatly the acreage devoted to this plant may well lead to an increase

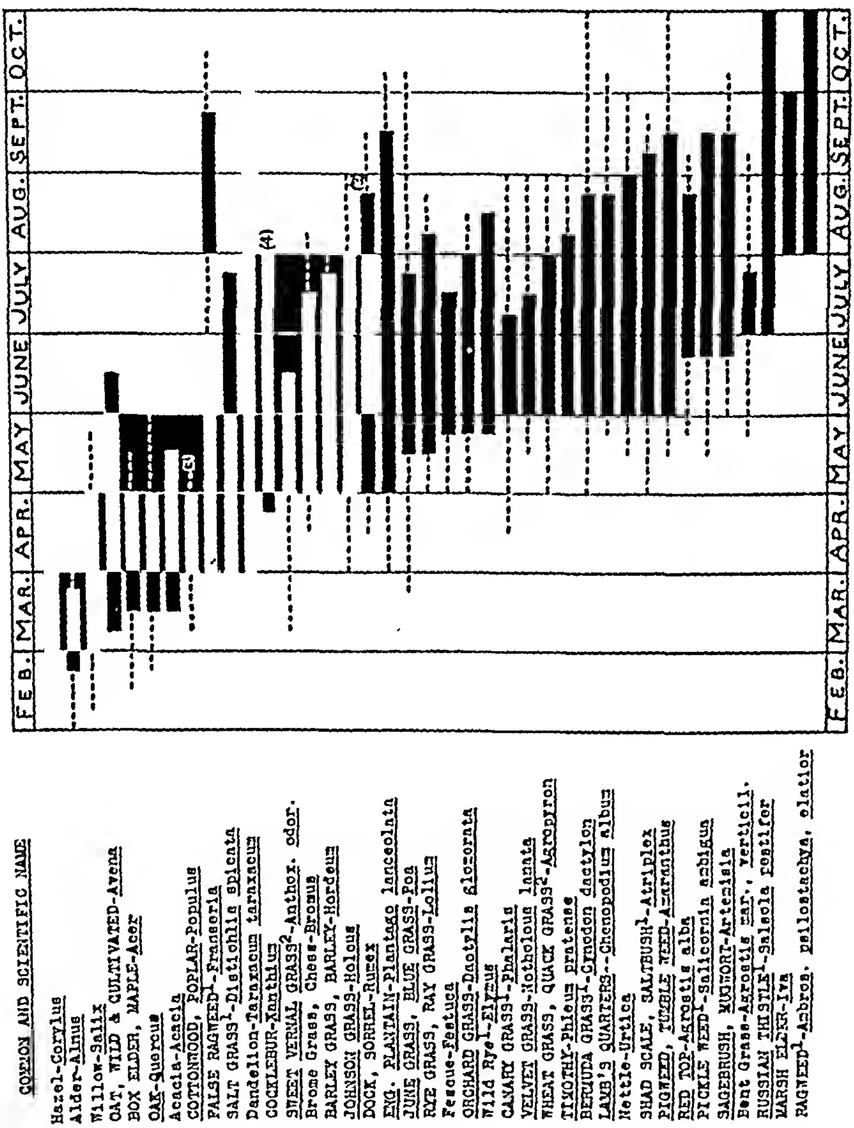

Fig. 9.—Pollination calendar for Zone VIII. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type, respectively. *1*, None in northern portion; *2*, much less common in southern portion; *3*, pollinates one month earlier in southern portion; *4*, pollinates later in extreme southern portion.

in the number of such cases. McMinn and Graham[65] found that the pollen of the mirror plant (*Coprosma baueri*), an ornamental shrub widely planted in California and pollinating from the beginning of April to the end of June, yields positive skin tests in a considerable group of patients with hay fever. Langley[140] reported an unusual case of hypersensitiveness in a nurseryman to the pollen of an exotic plant, *Piqueria trinervia*, due to hothouse exposure through the winter. One of us (E. U.) encountered two exceptional cases in which hay fever

was evoked by the pollens of tree of heaven (*Ailanthus glandulosa*) and horse chestnut (*Aesculus hippocastanum*), respectively. Mention should also be made here of the possibility of allergy to insect-borne pollens under appropriate conditions.

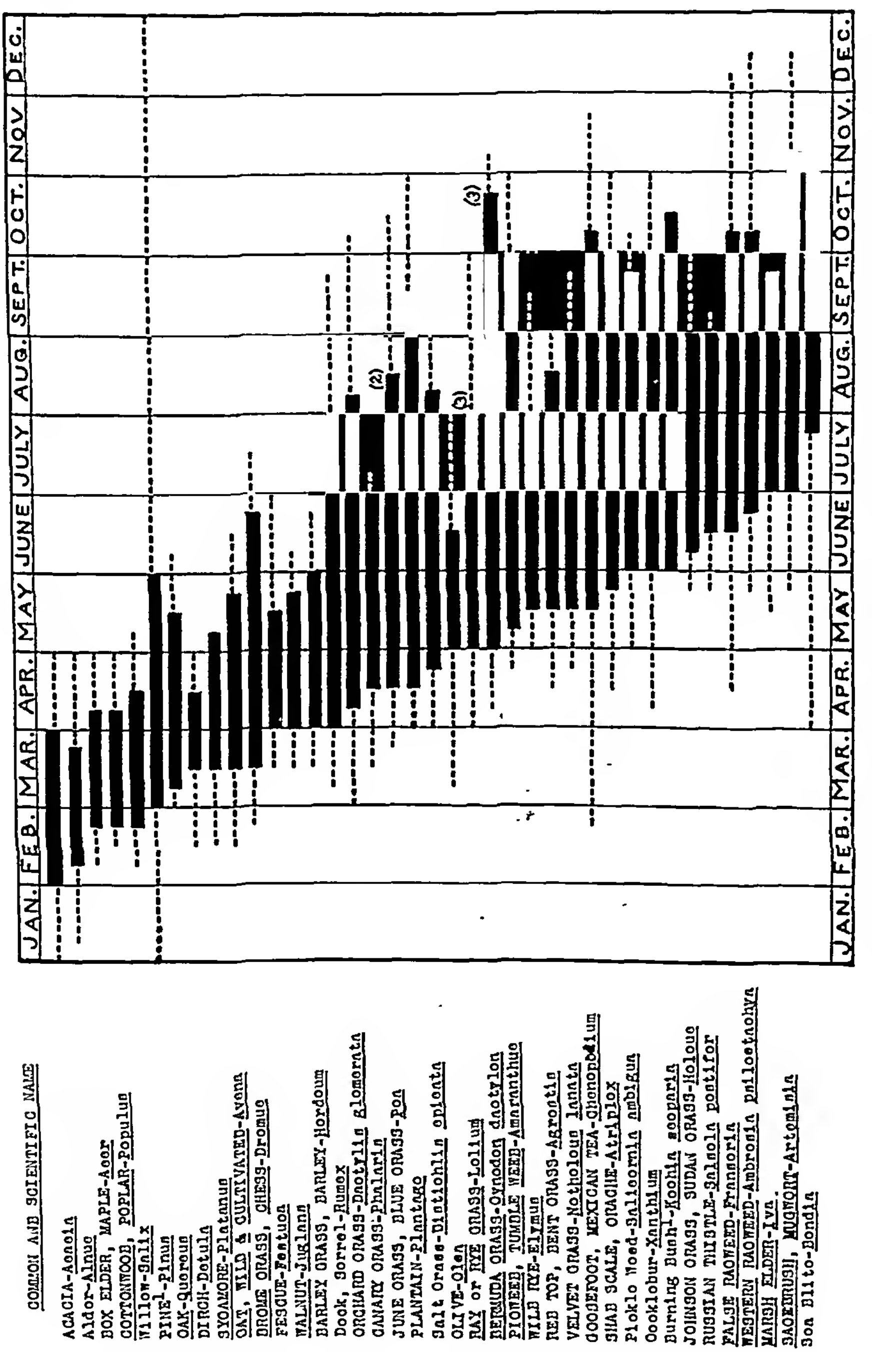

FIG. 10.—Pollination calendar for Zone IX. Most important pollens, those of secondary importance, and the least important are indicated by underscored capitals, capitals, and capital and lower case type respectively. *1*, Less common in southern portion; *2*, pollinates perennially in certain areas; *3*, pollinates perennially in southern portion.

A third important source of error lies in the fact that, even within a relatively small area, differences in the elevation above sea level play a significant part in advancing or delaying the date of first pollination by a month or more.

This applies, for example, to the variations in pollination time in a valley and the adjacent mountains. As mentioned above, for each 400 feet of altitude, the delay amounts to about four days. It has also been observed (Mullin[77]) that the nature of the flora present varies greatly with increasing altitude.

Despite all these obvious and inevitable faults, such tabulations of data as the pollen calendars are certainly of great general value to the physician as a guide in the diagnosis and treatment of hay fever.

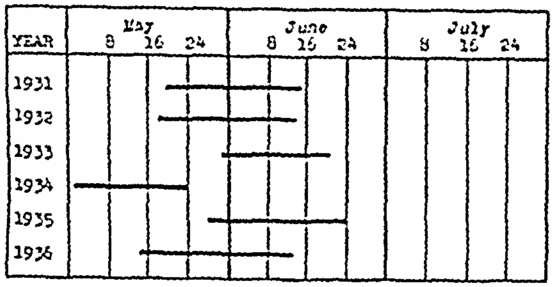

Fig. 11.—Pollination times of a single plant (orchard grass—*Dactylis glomerata*) in six successive years. Note the marked variation (as much as four weeks) in the onset and cessation of pollination in certain years.

It must be admitted that some of the plant prevalences and pollination dates presented here are not always in accord with the accepted ideas. It can only be said that they represent a careful, impartial evaluation of the published material after the elimination of the apparently less reliable observations. This accumulated information cannot be considered as final but could well be supplemented by further surveys, preferable on a nationwide scale and according to a uniform technique. The desirability of this and the locations in which it is most needed will be discussed in a separate article.[3]

SUMMARY

The necessity for a thorough knowledge of the distribution, prevalence, and pollination dates of the trees, grasses, and weeds which cause pollinosis is well known.

For this purpose, the United States has been divided into nine zones, according to botanical considerations. The plants which most commonly produce hay fever, their pollination times, and their relative importance are presented in nine pollination calendars, one for each zone.

SURFACE FILMS FORMED BY BLOOD PLASMA AND SERUM OF PATIENTS WITH CHRONIC ARTHRITIS*

C. WESLER SCULL, PH.D.,† AND RALPH PEMBERTON, M.S., M.D.‡
PHILADELPHIA, PA.

INTRODUCTION

PATIENTS with chronic arthritis present deviations from normal in respect to both the cellular and noncellular components of the blood. Anemia[1] is common, and moderate leucocytosis and relative increments in the proportion of aged neutrophiles are frequent. Few significant alterations from normal have been found with respect to the fasting levels of substances having small molecular weights and high solubility in water, such as sugar, urea, and electrolytes.[2] While none of the abnormalities of blood thus far described are pathognomonic for the rheumatic syndrome, they are significant in that they reflect evidence of systemic disturbances. Among newly available procedures which might be expected to throw additional light on the nature of the pathologic alterations in the fluid tissues of arthritis is one which depends upon the formation of surface films by the substances known to be present in the blood in altered amounts. Abnormal levels of globulin and albumin in the blood of certain clinically active atrophic arthritic patients have been demonstrated in this[3] and other laboratories.[4, 5] These deviations are associated with decreased suspension stability of the erythrocytes and with gelation of plasma upon the addition of formaldehyde.[6] Blood sera from comparable cases show agglutinins for hemolytic streptococci.[7]

Purified proteins and lipoids possess the quality of spreading on the clean surface of an aqueous substrate to form thin films. Such films have been extensively studied by Adam,[8] Langmuir,[9] Langmuir and Schaefer,[10, 10a, 10b] Harkins,[11] Gorter,[12, 12a] Blodgett,[13] and many others. A recent review by

*From the Department of Rheumatoid Diseases, Abington Memorial Hospital, Abington, Pennsylvania.

Supported in part by a fund in memory of Alexander B. Coxe and by a fund in memory of Dr. Angenette Parry.

Received for publication, October 1, 1942.

†Instructor in Chemistry, Assigned to Medicine, Graduate School of Medicine, University of Pennsylvania.

‡Professor of Medicine, Graduate School of Medicine, University of Pennsylvania.

Gorter[14] includes a comprehensive bibliography covering particularly studies on films produced by compounds of biologic interest. The surface films produced by various substances exhibit characteristic qualities with respect to extent, viscosity, compressibility, thickness, and structure. Such films may be formed by remarkably small amounts of material. Under appropriate conditions certain materials spread spontaneously to form films which are only one molecule in thickness. The small quantities required for observation and the characteristic qualities exhibited by physiologically important compounds, such as lipoids and proteins, suggest the possibility that the procedures developed in this field might be well adapted to the study of body fluids in health and disease.

The present report presents results of an exploratory survey made to ascertain the extent to which methods of surface film study are adaptable to clinical materials, especially as presented by patients with rheumatic diseases. A relatively simple technique based upon more elaborate methods used in the study of surface films formed by purified oils, fatty acids, other lipoids, and proteins has been devised; this reveals differences between blood fluids obtained from certain rheumatic subjects and from control subjects. A completely satisfactory interpretation of the significance of the differences encountered would require an extended and exhaustive analysis of each component fraction of the complete fluid. Such an analysis is beyond the scope of the present survey. The data available, however, disclose a new physical index of systemic deviations from normal in the arthritic patient. It appears probable that comparable deviations occur in other clinical conditions, and application of the technique described is not limited to rheumatic disorders.

CLINICAL MATERIALS

Patients from whom blood specimens were obtained for study were in the dispensary, ward or private services of the Abington Memorial Hospital, primarily because of rheumatic complaints. The general class of rheumatic disease, together with relevant records regarding the clinico-pathologic picture, is indicated with individual data on the surface films formed by the specimens.

APPARATUS

The apparatus and general procedure represent an adaptation of methods described by Langmuir.[10] Details of construction are presented, not only to indicate fully the conditions under which data were secured, but also to show that semiquantitative results can be secured even though commercial models of surface film balances or elaborate facilities for the construction of instruments are unavailable. A rectangular tray of brass was made by attaching tapped square rods (3/8 in.) with screws to the edges of a brass plate 30 × 8 × 1/8 in. A second rectangular enclosure was made by attaching similar square rods within the first at a distance of 1/4 in. from the sides and 1 in. from the ends. The second enclosure provides a water bearing which automatically guides a floating barrier used in the preparation of plates with built-up films. Blodgett[13] has demonstrated that layers of barium stearate can be used to afford a

measure of the thickness and homogeneity of films of unknown composition. The tray was fitted with a well 1 in. in diameter and 3 in. deep, 5 in. from one end of the tray. The inside of the tray was painted with black Duco, which serves several purposes; viz., seals the edges, makes materials floating on the surface of the water readily visible, and prevents contamination of the substrate by metallic ions from the tray. Before use, the inside of the tray and the edges were coated with paraffin in order to make them hydrophobic.

To facilitate measurements of area, one edge was marked off in ½ centimeter lengths. In order to provide an index of the forces exerted by films a chain balance was suspended six inches from one end of the tray. This balance consisted of a beam (made from bicycle wheel spokes), a knife edge (one-half of a safety razor blade), supported on a bearing made by depressing angles in a glass rod. Lateral forces exerted by the film were transmitted to the beam by way of a vertical extension from the beam loosely attached to a float of mica, 5¼ in. by ¾ in. In order to prevent movement of the films around the edges of the balance float and at the same time to permit the necessary freedom of motion, the following arrangement was devised. The float was fitted at each end with thin steel strips with equilateral notches, ⅛ in. Similarly notched strips (segments of safety razor blades) were attached to the top of the inner edge of the tray. A floating adaptor was constructed by fastening a piece of mica (⅜ in. by ⅛ in.) at right angles to a strip of thin steel ½ in. × ¼ in. The latter was notched by a square ⅛ in. by ⅛ in. to accommodate the mica. This adaptor was coated with paraffin and placed between the edge of the tray and the balance. While permitting movement of the float of the balance, the adaptor prevents passage of any material on the surface water around the edge of the balance. Pressure exerted by the films being transmitted to the beam can be counterbalanced and hence estimated by raising or lowering the free end of the chain. The relative length of the chain supported by the beam provides an index of pressures exerted on the float. The relative magnitude of the forces encountered were estimated by calibrating the length of chain in terms of the known forces exerted by films of oleic acid (29.5 dynes) and castor oil (15.0 dynes). The construction and appearance of the apparatus are shown in Figs. 1 and 2.

PROCEDURE

After filling the tray with distilled water to a level of about $\frac{1}{16}$ in. above the edge, the surface was swept clean by a sliding paraffin-coated chromium-plated brass rod from the balance toward each end of the tray. Materials floating on the surface were thus confined to the ends of the tray. Such sweeping was repeated four or five times. As a result of these measures the surface of the water was made essentially free from gross contamination. On standing, under conditions prevailing in our laboratory, a film of essentially constant size accumulated on the working area, as shown by moving a swing of the balance from a poised position when a barrier was advanced toward the float. Unless the area of this blank exceeded 10 sq. cm. it was assumed that there was no significant source of contamination in the tray. As a result of

observations on the blood plasma of about thirty arthritic subjects, it became apparent that the materials in approximately one cubic millimeter of plasma produced films which could be handled within the working area. In view of the difficulties involved in the direct discharge of this small volume of fluid from available measuring apparatus, it was necessary to dilute the sample. One c.c. of blood plasma or serum was diluted with 4 c.c. of 0.85 per cent sodium chloride solution. Five cubic millimeters were discharged from a differential pipette. While some encouraging results were secured by the direct transfer of a droplet of the diluted sample from a pipette to the surface of

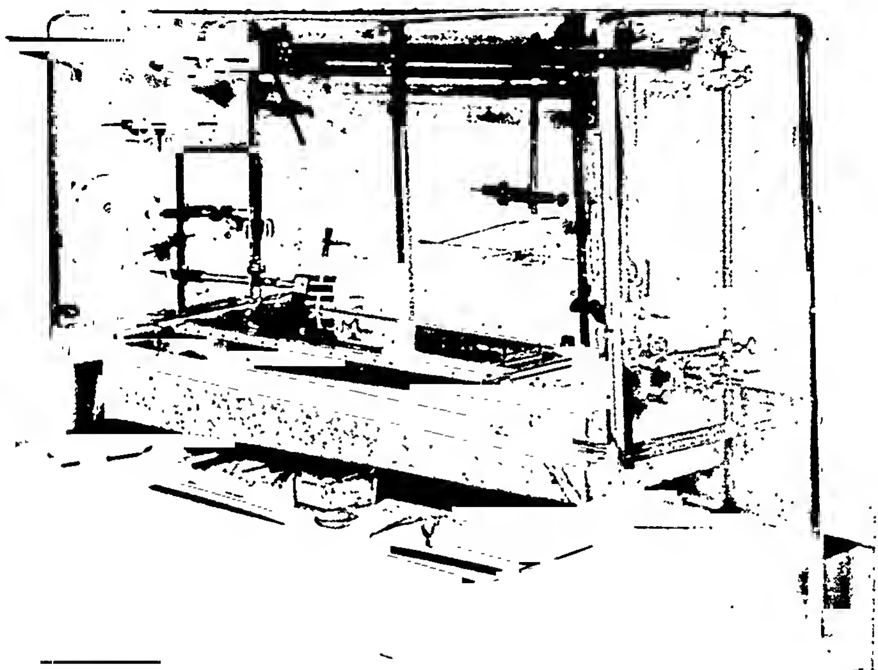

Fig. 1.—Photograph of surface film balance showing construction and arrangement of parts.

water, reproducible results were not secured with satisfactory uniformity. It was learned that more nearly reproducible data were obtained by the intermediate transfer of the diluted specimen to a metal plate. The plate held in a vertical position was then lowered cautiously through the prepared surface of water until the specimen made contact with the latter. The film-forming materials spread to the free surface of the water. After standing for five minutes the plate was dipped several times in order to insure the transfer of all of the specimen. Whether the improved reproducibility of results was actually due to this step or to increased skill in manipulation has not been established. The data presented here were secured by this procedure. The quantity of film-forming material so introduced was insufficient to cover the entire area of the tray. The films could be moved on the surface by slowly advancing the barrier toward the balance until the latter moved away from the poised po-

sition. The barrier used for maneuvering the film was fitted with a glass slide cemented on at right angles, thus functioning as a T-square. The longitudinal extent of the film was then noted, together with the weight required to counterbalance the force exerted by the film. Successive decrements of area were made by advancing the barrier by steps of ½ cm. This was followed by mak-

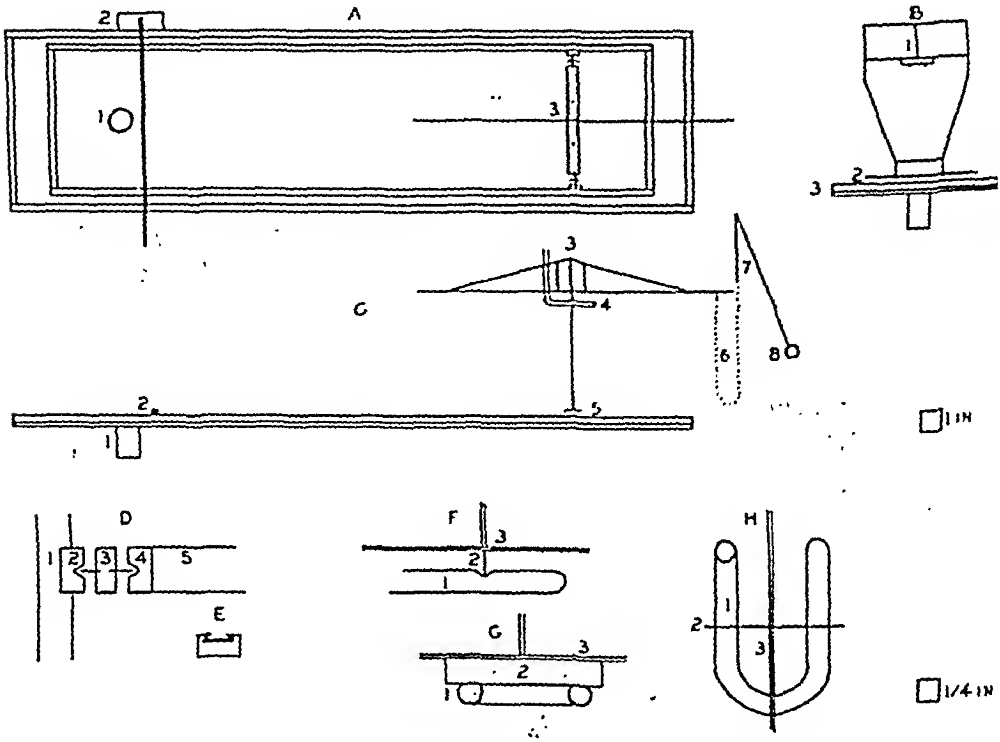

Fig. 2.—Line diagrams showing construction of surface film balance. Description:

ing corresponding adjustments of the balance. Force-area charts were constructed by plotting the area in square centimeters as abscissa and the force in dynes as ordinate. The force-area diagrams so produced by different specimens were then compared by inspection.

RESULTS

In order to indicate the range of values secured by repeated determinations with the same specimens of blood, representative data are shown in Fig. 3. While the points in these instances are not identical, variations are sufficiently close to permit a satisfactory comparison of areas covered at any convenient reference pressure. Data secured with other samples were at least equally

satisfactory. It may be observed that a significant difference in area appears between the films produced by plasma and serum of the same blood. Differences of corresponding magnitude appeared between fresh and old plasmas from rapidly sedimenting bloods.

Data showing the range of representative data encountered among specimens from arthritic patients are shown in Fig. 4. While inspection reveals some differences in the slopes of the force-area curves, these are too small to be considered significant; however, the range of variations of film size are too great to be referred to variations in technique alone and must be regarded as real. Variations in area from 150 sq. cm. per 1 c.mm. plasmas to 545 sq. cm. per 1 c.mm. plasma were encountered.

Curve VC represents the force-area diagram produced by a surface film formed by plasma from a patient with the most extensive and severe active atrophic arthritis in the entire series. This patient died one month later with a pathologic diagnosis of amyloidosis with atrophic arthritis. At the time of the last observation the total protein was only 4.4 Gm. per 100 c.c. Curves CD and DL represent data from patients with active arthritis, each of whom presented sedimentation rates of 1 mm. per min., but with a total protein of 7.2 Gm. per 100 c.c. Curve PP represents another normal control subject with a normal sedimentation rate. MP represents a case of hypertrophic arthritis which is intermediate between the normal subjects and atrophic arthritic patients.

DISCUSSION

Although the initial and final portions of the force-area curves of the several films are variable, the middle portion approximates a straight line. For limited purposes it may be assumed that extrapolation of this segment of the curve to the base line represents the effective area covered by the film at "zero" pressure, or more accurately, a suitable reference pressure. Obviously, any other selected pressure within the limits of 13 to 15 dynes could be used as a reference point. It is conceivable that the first swing of the balance is produced by an extended portion of the film only or a "gaseous" film. For this reason an appreciable amount of compression is essential in order to provide assurance that the apparent area of the tray is covered by a substantial film. A constant increment of pressure with decreasing area may be regarded as indicating the formation of a reasonably stable film. The final stage, characterized by a relative decrease in pressure with diminishing area, may be attributed to collapse, folding or submersion of the film. The possibility that some components of the film are forced into solution cannot be disposed of by data at hand. The release of pressure after compression in excess of 15 dynes did not uniformly yield a film equal in area to that of the original.

It is probable that the film formed by blood fluids is composed of several substances. Certain components of blood are known to form surface films when used alone. Lipoids, i.e., fatty acids and sterols, and proteins are known to possess film-forming properties. Furthermore, surface films of mixed composition have been prepared from several of the aforementioned classes of

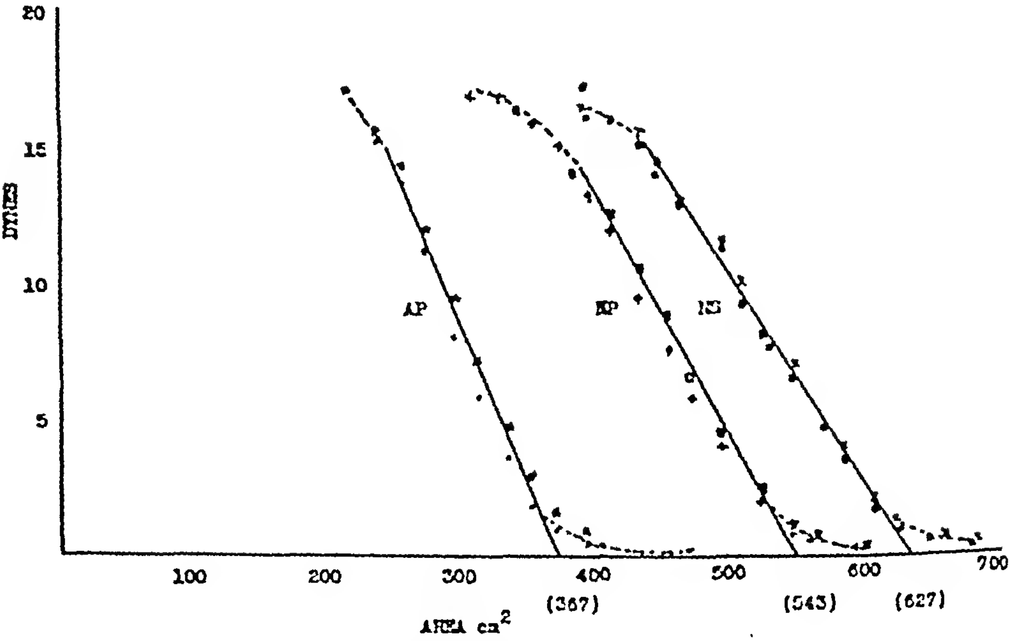

Fig. 3.—Chart showing comparative data in repeated determinations of the pressures exerted by surface films when confined to progressively decreasing areas. These films were produced from one cubic millimeter of plasma or serum from normal and arthritic subjects. AP, atrophic arthritic plasma; NP, normal plasma; NS, normal serums. From left to right, subjects: DR, WS, WS.

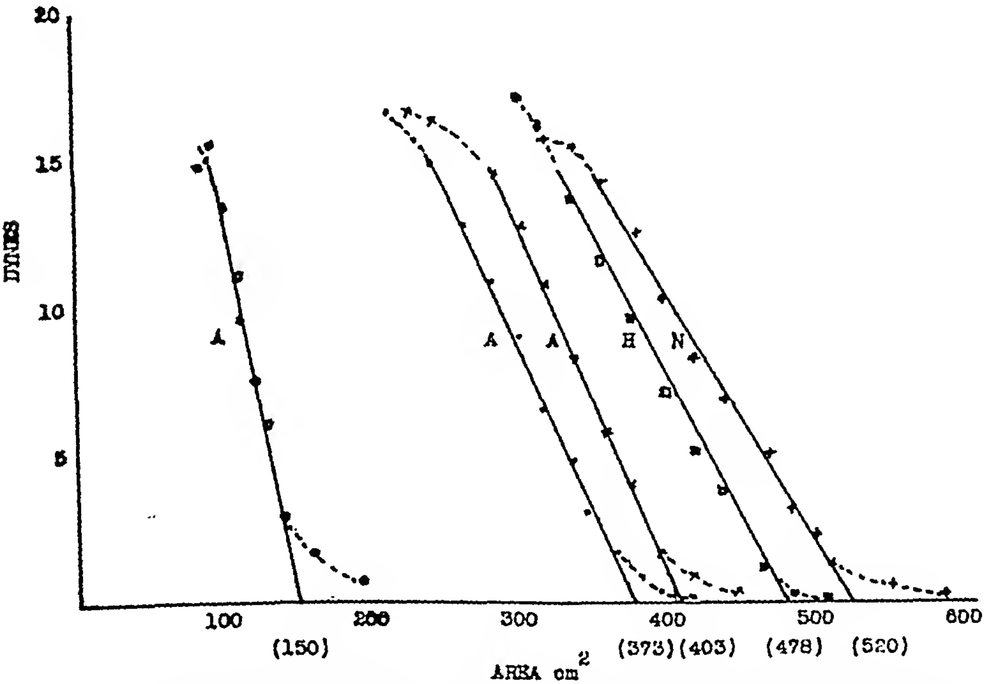

Fig. 4.—Chart showing the range of force-area curves of films produced by one cubic millimeter of blood plasma from representative arthritis: A, atrophic; H, hypertrophic; N, normal. From left to right, subjects VC, JD, DL, MP, PP.

compounds. A full account of the role of the individual compounds of the surface film formed by blood serum is beyond the scope of the present exploratory study.

The values recorded are not to be regarded as absolute and might vary with different techniques. There can be little doubt, however, as to the reality of the relative differences observed. The films formed by materials from blood serum are probably at least 25 per cent larger in area than can be accounted for by the proteins contained in them, even on the assumption that the latter are present in their most extended state. It is conceivable, however, that modifications in spreadable qualities may occur during the process of isolation of the proteins.

Another point of interest is the apparently larger areas of the films produced by serum as compared with those of plasma. This is particularly noteworthy inasmuch as fibrinogen, a spreadable material, is absent from the serum. This suggests that the reactions leading to the formation of fibrin from fibrinogen liberate materials with spreadable qualities. Determinations of film areas produced by a given plasma repeated at daily intervals revealed substantial increments. In vitro ageing of certain plasmas apparently involves a liberation of film-forming material. It is further relevant to call attention to the possible correlation of increased spreadability of serum and the suspension stability of the erythrocytes. Cells which settle rapidly in pathologic plasmas settle much more slowly in the corresponding serum and in aged plasma. These facts suggest that serum and aged plasma increase the suspension stability of red cells because of the relatively large amounts of film-forming substance as compared with the quantities present in fresh plasma. An alternative explanation based upon dilution of plasma by fluid from cells due to excessive salt concentration; viz., sodium oxalate, is not to be completely dismissed although this influence appears to be minimal.

While it may be considered possible that differences in the physical qualities of the film formed by blood serum with a high level of globulin might differ from that containing normal globulin concentrations, data presented by Gorter[11] would appear to minimize this probability. Several blood proteins, although widely different in general physical qualities, spread to form films of essentially the same magnitude. Thus both pseudoglobulin and fibrinogen form films to the extent of one square meter per milligram. Serum albumin which differs markedly from both of the former, in respect to molecular weight, electrophoretic mobility and solubility, spreads to form a film only 2 per cent less in area. Apparently such differences as may be presented by pathologic specimens are not directly related to differences in the protein components alone.

According to press reports Langmuir[15] has patented the use of the variable thickness of surface films for the diagnosis of disease. For this reason preliminary observations on the thickness of these films by the method of Blodgett,[13] although initiated, were not further pursued in the present studies.

The adaptability of the procedure to the study of clinical materials has been reasonably well established, and the method affords a practical means

of studying extremely small quantities of biologic fluids. Comparison of the spread of a mixed film with the sum of the areas of its components may afford a means of detecting otherwise unknown substances in body fluids.

A comparison of data on various arthritics with controls suggests that patients showing the greatest general systemic involvement and clinical activity present the greatest departures from normal insofar as areas of surface films are concerned. Such deviations from normal are in the direction of lowered rather than increased areas. It appears likely that certain nonarthritic patients, particularly those with lowered levels of plasma albumin, may exhibit a similar departure from normal. For this reason, deviations from normal areas of surface films are not to be regarded as satisfactory solitary indices of the arthritic process per se. Regardless of the precise interpretation to be placed upon the surface films from blood plasma of the arthritic patients, it is evident that the illness of the rheumatic patient involves more than disturbance in joints.

SUMMARY

A brief survey of an adaptation of procedures employed in the study of surface films directly to clinical materials reveals suggestive possibilities. A semiquantitative technique for the production and study of films on the surface of water from small amounts (one cubic millimeter) of blood serum and plasma has been developed. Differences have been observed with respect to the areas of films produced by equivalent volumes of normal and pathologic specimens. The areas of film formed by blood fluids from patients with rheumatic disorders are frequently smaller than those produced by blood fluids of normal subjects. One cubic millimeter of normal plasma produced films with areas of 550 sq. cm., whereas the same quantity of plasma from certain severely ill atrophic arthritic patients produced films ranging from 150 to 450 sq. cm. Films produced by plasma from less acutely ill arthritic subjects attained more nearly normal areas. These data show that the rheumatic patient suffers from a disorder of the physicochemical pattern of his blood as well as from a pathologic process in his joints.

While these deviations apparently bear a general relation to the degree of systemic involvement, they should not be regarded as pathognomonic for arthritic diseases. Some evidence is presented indicating the probability that a major factor determining the magnitude of the films relates to variations in the concentration of proteins in the specimens studied. Full interpretation of the observed differences requires more data than are now available, but there are reasonable grounds for the speculative view that certain physiologic consequences must follow upon a reduction in the "film-forming stuff" in body fluids. An evaluation of the role of film-forming capacity of blood fluids in physiologic processes and the modifications in pathologic states invites further inquiry.

VITAMIN A AND THE DETOXICATION OF MONOBROMOBENZENE*

FRANK L. HALEY, M.D., AND GEORGE S. SAMUELSEN, M.A., BROOKLYN, N. Y.

THE vital relationship of cystine to insulin, glutathione and other functionally important sulfur compounds, led us to experiment with monobromobenzene, which according to White and Jackson[1] and Stekol,[2] is specifically detoxicated by the sulfur containing amino acids, removing them from the normal nutritional processes.

In our experiments,[3] animals were fed quantities of monobromobenzene far in excess of the amount that could have been detoxicated if all of the sulfur compounds of the diet were utilized for that purpose, and led us to suspect other modes of detoxication.

Goerner[4] working in this laboratory has shown that certain carcinogenic hydrocarbons cause a rapid depletion of the liver vitamin A. This suggests that this vitamin may play a role in the detoxication of aromatic hydrocarbons and related compounds.

*From the Department of Biological Chemistry, Long Island College of Medicine, Brooklyn, N. Y.
Received for publication, October 8, 1942.

In this work we have attempted to show a relationship of the vitamin A content of liver tissue to the detoxication of monobromobenzene.

EXPERIMENTAL

The experimental work is divided into three phases. The first phase is a study of the effect of injected monobromobenzene on vitamin A deficient rats; the second, the feeding of monobromobenzene to normal rats and determining its effect upon the liver vitamin A level; and the third, the measuring of the effect of subcutaneous injection of monobromobenzene at various levels over various time intervals upon the liver vitamin A level.

Experiment No. 1.—A small series[12] of white rats that had been depleted of vitamin A by the U.S.P. method and an equal number of normal control animals were given subcutaneous injections of 100 mg. of monobromobenzene in the form of a 10 per cent solution in corn oil.

All of the rats in the vitamin A depleted group died within 48 hours after injection, while the normal animals showed no harmful effects.

Experiment No. 2.—A group of 20 adult white rats, designated A, were placed upon a normal laboratory feed (0.54 per cent S) that had been supplemented with 2 per cent of monobromobenzene. The monobromobenzene was incorporated by mixing it with twice its weight of corn oil before adding it to the stock diet. The prepared diet was stored in airtight containers. An equal number of control rats, designated B, were maintained on the unsupplemented stock diet. At intervals varying from three weeks to three months a few animals from each group were killed and their livers assayed for vitamin A content. The vitamin A was estimated by extraction according to the method of Moore[5] and the vitamin determined by the Andersen and Levine[6] modification of the method of Rosenthal and Erdelyi,[7] using a biologically standardized vitamin A concentrate as a standard for this colorimetric procedure.

The results of this experiment are tabulated in Table I.

Experiment No. 3.—Four series of adult white rats were placed upon a normal complete diet and given subcutaneous injections of monobromobenzene dissolved in corn oil (50 mg. per c.c. of oil).

Series A received 50 mg., series B 100 mg., series C 150 mg., of monobromobenzene, and series D 2 c.c. of corn oil without monobromobenzene.

The injections of monobromobenzene were made three times each week for a four-week period. At the end of this time the animals in all four series were killed and their livers assayed for vitamin A content (Table II).

DISCUSSION OF RESULTS

The first experiment shows that animals depleted of vitamin A have an extremely low capacity to withstand the toxic effect of monobromobenzene. This poor resistance cannot be entirely related to the absence of vitamin A, since such animals are in poor physical condition.

In the second experiment the lower vitamin content of the animals receiving the monobromobenzene is definite evidence of a harmful effect of this agent.

TABLE I

GROUP A			GROUP B		
RAT NO.	NUMBER OF DAYS ON DIET	TOTAL VITAMIN A CONTENT OF LIVER	RAT NO.	NUMBER OF DAYS ON DIET	TOTAL VITAMIN A CONTENT OF LIVER

19.	92	400 units	39.	92	880 units
20.	92	350 units	40.	92	1030 units

Group A received 2 per cent monobromobenzene in diet.
Group A lost 0.11 grams per rat per day while on diet.
Group B lost 0.06 grams per rat per day on the normal diet.

TABLE II

SERIES A		SERIES B		SERIES C		SERIES D	
RAT NO.	TOTAL LIVER VITAMIN A	RAT NO.	TOTAL LIVER VITAMIN A	RAT NO.	TOTAL LIVER VITAMIN A	RAT NO.	TOTAL LIVER VITAMIN A
51.	760 units	61.	440 units	71.	800 units	81.	880 units
52.	830 units	62.	760 units	72.	1260 units	82.	750 units
53.	270 units	63.	910 units	73.	850 units	83.	910 units
54.	680 units	64.	900 units	74.	1020 units	84.	390 units
55.	1100 units	65.	650 units	75.	800 units	85.	1100 units
56.	940 units	66.	870 units	76.	590 units	86.	850 units

Series A received 50 mg. monobromobenzene three times each week.
Series B received 100 mg. monobromobenzene three times each week.
Series C received 150 mg. monobromobenzene three times each week.
Series D received no monobromobenzene.

It cannot be assumed, however, that the vitamin decrease is directly due to its action in detoxifying the monobromobenzene, since there is the possibility that the monobromobenzene interferes with the absorption of the vitamin of the diet. The fact that only minor weight changes occurred during the experimental period proves that any interference with the absorption processes is not extensive.

The injection procedure of the third experiment did not cause a noticeable change in the liver vitamin A level and proves the lower vitamin A levels obtained in the second experiment are not due to a detoxication process but are possibly associated with a failure to absorb the vitamin from the intestinal tract in the presence of the monobromobenzene.

SUMMARY

Vitamin A does not appear to be associated with the detoxication of monobromobenzene, although vitamin A deficient animals have a lowered resistance to this toxic agent.

There is some evidence that monobromobenzene interferes with the absorption of vitamin A.

SYRINGADENITIS SUPPURATIVA TROPICALIS (A COMPLICATION OF LICHEN TROPICUS)*

HISTOLOGIC APPEARANCE AND ETIOLOGIC CONSIDERATIONS PARTICULARLY AS TO A POSSIBLE RELATIONSHIP OF ASCORBIC ACID AND CARBOHYDRATE METABOLISM

FREDERICK REISS, M.D., SHANGHAI, CHINA

THE observation has been made by competent observers that few persons in the tropics escape being affected by lichen tropicus (prickly heat). Those without prior history of attack are generally free or are mildly affected during their stay in hot climates, whereas those previously affected are usually subject to subsequent and increasingly severe attacks of this very annoying disease. Only a limited number of patients with prickly heat develop complications in the form of multiple furuncle-like lesions. Since only a few references have been made in the literature to this complication, it was considered important to present the subject not only from a general climatic-pathologic but also from a dermatologic point of view.

Without going into a detailed discussion, it should be noted that no acceptable explanation has been yet offered regarding the cause of lichen tropicus. Unna[1] considered it an inflammatory disease of the sebaceous glands but also was

*From the Division of Dermatology and Syphilology, National Medical College, Shanghai, China. (Chief: Frederick Reiss, M.D.)

Received for publication, October 21, 1942.

aware of an edematous swelling and obstruction of the epidermal cells due to disturbances of sweat secretion. Pollitzer[2] was partly in agreement with Unna[1] and he emphasized the obstruction of the flow of the sweat with subsequent sweat imbibition and swelling of the epidermal cells. Kayser[3] stressed the irritating effect of urea and sodium chloride of the sweat, whereas Ziemann[4] finds an explanation in high atmospheric humidity. Acton[5] speaks of an inflammation of the sweat glands caused by staphylococci and Smith[6] considers *Monilia* as the etiologic agent. Very little investigative work has been done to shed light upon the complications of the subsequent suppurative involvement of the sweat glands. Most textbooks make few references to it and many do not even mention the existence of these after-effects of prickly heat. Castellani[7] stated that "occasionally the vesicles may become purulent and crops of boils may develop." Manson-Bahr[8] agreed that prickly heat is a common though an indirect cause of boils; for the "breaches of surface following on the scratching it induces afford many opportunities for invasion of the micro-organisms of furuncular disease." Plehn[9] (in Mense's handbook) refers to the lack of cleanliness and scratching which may be blamed for extensive lesions and deep suppurations. In recent literature Acton and Smith[5, 6] make brief mention of its occurrence in India and Nigeria, respectively. G. Pernet's[10] histopathological interpretation of Radcliffe-Crockers case of acne agminata should, however, be mentioned, this being the first observation of similar nature. "The primary change appeared to occur about the sweat coils which were more or less disorganized by an inflammatory leucocytic infiltration. In parts, a hair follicle had also become involved and necrotic changes had taken place in the central parts of the infiltration. There is also a perivascular infiltration. The origin about the sweat gland agreed with the clinical evolution of the individual lesions, which commenced in the deeper parts and gradually came up to the surface with suppuration. The disease had started somewhat suddenly, about the end of August, 1901, while the patient was at the seaside for his holiday. No plasma cells were found by Pappenheim's method; few sections were stained for tubercle bacilli with negative results."

CLINICAL APPEARANCE OF LICHEN TROPICUS

Lichen tropicus (prickly heat) makes its appearance when the temperature is around or above 90°, in regions with high atmospheric moisture. The onset is characterized by a severely itching disseminated, follicular, periporitic vesicular eruption which the naked eye would recognize as a small follicular macule. The most favored regions are the covered parts of the body, especially the flexoral folds where often the eruption first appears. Only exceptionally is the face more severely involved than the rest of the body. The tiny vesicles soon become turbid, rupture, and occasionally an eczema-like plaque appears which adds to the already existing irritation. With the change to cool weather or when proper treatment is given, the eruption subsides. This is followed by a fine desquamation.

A Complication of Lichen Tropicus.—As already pointed out, only a limited number of people show severe involvement of the face and these are the persons who are frequently subject to a peculiar complication. Though itching may

be absent on the face or be considerably attenuated, there appears instead a growing sensation of tension over the face (rarely over the buttocks or the submammillary regions) which is followed by the appearance of numerous painful split-pea-sized and larger superficial and deep nodules (Fig. 1). These lesions at the onset are covered by shiny red skin which, after several days, may either develop a purulent top with subsequent suppuration of deeper portion of the lesions, or the lesions may disappear after four to eight weeks by absorption. Many weeks after the disappearance of the lesions there still remains a visible trace in the form of a distinct hyperpigmentation. Scarring occurs occasionally. The course of the disease is limited to from one to two and one-half months, during which time patients are incapacitated, not only on account of the un-

Fig. 1.—Profuse outbreak of nodular lesions with limited involvement of the upper and lower eyelids. Note the complete freedom of the center of the upper lip and of the chin.

Fig. 2.—Lesions are numerous on the bridge of the nose and forehead, but the periocular or perioral regions are hardly affected.

sightly appearance but at times also on account of pain and constitutional symptoms. Regional lymph nodes are slightly enlarged but never suppurative. This complication has been named syringadenitis suppurativa tropicalis.

Occurrence of the Complication.—Of twenty cases personally investigated, the face alone was affected in sixteen. The forehead and the bridge of the nose showed the severest involvement, whereas the periocular region, the upper lip, especially the center (philtrum) and the lower lip and chin were free (Fig. 2). In two cases a few nodules developed on the buttocks of two men and in two women a few lesions were observed under the breasts. In not a single instance were the axillae, the palms or the soles involved.

HISTOPATHOLOGY OF THE COMPLICATION

On account of the site of the lesions only a very limited number of women gave their consent for biopsy. Microscopic examination of the 20 cases were therefore made in only 8 instances. In four cases serial sections were made.

Epidermis.—In general the epidermis shows the following characteristic changes. In the majority, a distinct enlargement of the sweat and follicular orifices is observed. In an equal number of cases a subcorneal cavity is filled with detached, poorly staining cells, serofibrin and in later stages with leucocytes and organisms. The pustules are intraepidermal (producing splitting of the layers), the floor being composed of an edematous rete malpighi and the roof of lightly stained edematous prickle cells. The contents showed necrotic cells, leucocytes, and cocci. The surrounding area is distinctly edematous. These changes correspond to the position of sweat glands and in sections one can frequently trace an inflammatory focus above a sweat gland.

Corium.—The corium is the seat of major changes (Fig. 3). The papillary capillaries are dilated and surrounded by leucocytes and lymphocytes and occa-

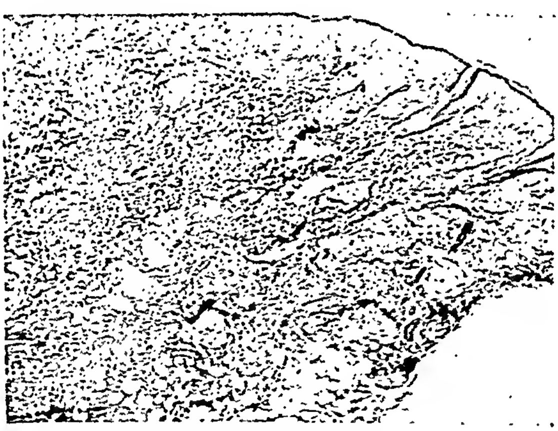

Fig. 3.—Low power photomicrograph showing: dilated pilosebaceous orifices; cellular breakdown above a sweat gland, with partial involvement of the coils.

sional plasma cells. The sweat ducts are also distinctly dilated and invaded by leucocytes and poorly staining cocci. This change increases with the beginning of the sweat duct. Not a single duct shows a cellular breakdown. The area above the sweat gland is generally the seat of cellular disintegration where small cavities are formed filled with necrotic cellular debris, leucocytes, and cocci. The coils are frequently also involved in the disintegrating process; there is no conclusive evidence as to whether the primary seat is the glandular parenchyma or whether the infection is transmitted through the duct or from the surrounding area. But it seems very suggestive that the infection travels partly via the sweat duct. Rarely, perifollicular abscesses involving the sebaceous glands are noticed. Most of the sections, however, reveal a tendency for abscess formation to develop above the sweat glands and only in rare instances is the localization a haphazard one. The cutaneous lymphatic spaces are dilated and infiltrated with inflammatory cells. At times one gains the impression as if the process would spread by the lymphatics.

CLINICAL NOTES

Our investigation of syringadenitis suppurativa tropicalis was carried out during the months of June, July, and August in 1939, 1940, and 1941 and is based on the observation of twenty Chinese patients (eighteen females, two males). The youngest was 17 years of age and the oldest 26. While this report deals only with Chinese, it should be noted that a similar complication is occasionally met with in other races in the same locality, whose occupation demands an outdoor life (at times also after long games of tennis, golf, etc.). A striking feature in our cases was the prevalence of the disease on the face and the predominating number (90 per cent) of young women (farmer, gardener class). Lack of cleanliness of the face can be safely discarded as a possible cause because the Chinese indulge in frequent wiping of their faces with towels dipped in boiling water. It could also be considered that scratching could be a contributory factor for infection. The fact, however, is the least irritated part of the skin and is hardly ever scratched. These possible exogenous etiologic factors were therefore partially eliminated and our attention was drawn to certain climatic and metabolic considerations. The staple food of the class of Chinese under our investigation consists of vegetables and polished rice. The intake of vitamin C during the summer is adequate and a nutritional insufficiency seemed unlikely. For the sake of comparison it should be mentioned that on account of the lack of green vegetables, the ascorbic acid level in the blood serum of the Chinese (in Peking) is considerably lower during winter. This, according to T. F. Yu,[11] is not due to racial difference because the serum ascorbic acid level goes up immediately as soon as ascorbic acid is added to the diet.

In tropical Java, de Haas[12] investigated the vitamin C serum level of Chinese and found that 0.86 mg. per cent was the average for 42 healthy persons. Our (unpublished) observations in healthy individuals during the summer months gave substantially the same results. We expected therefore that the excessive perspiration may cause an appreciable loss of vitamin C. This alteration may render the depleted skin susceptible to infection. Furthermore, a disturbed carbohydrate metabolism was expected, basing our supposition on the fact that an increased blood or tissue sugar content is favorable for the development of pyogenic infections of the skin. Our investigation included (1) blood serum vitamin C determination (according to Pijoan and Klemperer[13]), (2) blood sugar determinations (according to Hagedorn and Jensen).[14]

Serum Vitamin C Determinations.—Among the 20 patients investigated, the lowest level was 0.05 mg. per cent and the highest 0.78 mg. per cent. The average was 0.15 per cent. The daily administration of 200 to 300 mg. of ascorbic acid (Redoxon "Roche") increased the blood serum vitamin C level only moderately (10-20 per cent) during the period of excessive perspiration, whereas there was a definite rise with the onset of cooler weather and subsiding perspiration. This gives an indication of a possible partial pathomechanism for the vitamin C depletion and may also explain to a certain extent our difficulty in obtaining a saturation level of vitamin C during the period of excessive perspiration.

BLOOD SUGAR TOLERANCE TEST

Among the 20 eases investigated, the lowest fasting glucose level was 40 mg. per cent and the highest 70.5 mg. per eent making an average of 50.5 mg. per cent. After the intake of 1.75 Gm. of glucose per kg. of body weight, the blood sugar concentration showed a rapid rise (30-50 per eent) in the first fifteen minutes. After forty-five to sixty minutes, there was a drop of 15-20 per eent as compared with the initial rise. After two hours the level reached its highest peak with an increase of 40-50 per eent as compared with the fasting blood sugar level. After three hours, a 40-50 per eent inerease was still present. This pattern of blood sugar toleranee has been observed in 80 per eent of the cases that were studied. A typieal example is Chang Chen Chi, 17-year-old girl (O.P.D. No. 137149). (Chart 1.)

Glucose was not deteeted in a single speeimen of urine.

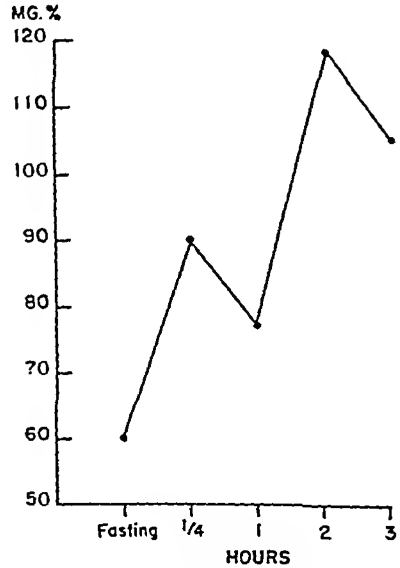

Chart 1.—Typical glucose tolerance curve.

INTERPRETATION OF DATA

In order to eorrelate the low serum ascorbic acid, with the low fasting blood sugar level, and the delayed glucose excretion, it may be of interest to recall the many investigations dealing with the relationship and with the effect of ascorbic acid on carbohydrate metabolism. It may be stated at once that there is a great variation in the reported results which is probably due to the different methods in use. While a number of investigators found that the administration of ascorbic acid to diabetics lowered the blood sugar; others such as Asinelli,[15] Mosonyi and Aszodi,[16] Stoïcesco and Gingold[17] and Tarsitano and Spena[18] found that the administration of ascorbie acid increased the level of blood sugar. Wille[19] found that vitamin C medication increased the blood sugar level especially under hypoglycaemic conditions. Stepp[20] and Schroder[21] and Altenburger[22] investigated the glycogen mobilizing effect of adrenalin. They found

a higher blood sugar peak after combined ascorbic acid medication in comparison with adrenalin alone. Kreitmair[23] confirmed these findings with his experiments on cats. Hamne[24] gave ample proof in his excellent monograph of the relationship of carbohydrates and vitamin C metabolism. According to his very carefully executed studies, the glucose tolerance curve showed an abnormal course in hypovitaminosis C. Not only was an excessive rise of blood sugar observed, but the post alimentary insulin secretion was provoked much later in comparison with cases with a normal vitamin C standard. It should be noted that animals kept on a low vitamin C diet develop a compensatory hypertrophy of the islands of Langerhans. (Rondoni and Montagnani,[25] Monasterio,[26] Borghi[27] and De Otto.[28]) These findings are parallel with the conclusions reached by Dessy and Doneddu[29] who found that both in normal persons and in diabetic patients intravenously administered ascorbic acid was recovered in greatly reduced amounts when a simultaneous intramuscular injection of insulin was given.

There is little doubt that the close interrelationship between the carbohydrate metabolism and vitamin C is firmly established. Apparently vitamin C plays in the carbohydrate metabolism the role of a bio-regulator. In other words vitamin C enters into the regulation of the blood glucose level in an important way in that it increases this level in hypoglycemia and decreases it in hyperglycemia. This interpretation would also offer a reasonable explanation for our findings.

Not only is the low fasting blood sugar level compatible and explicable with the low vitamin C blood serum level but the abnormal glucose tolerance test is a further characteristic in cases of vitamin C deficiencies. The high blood sugar curve after 2 hours indicates a lowered tolerance for carbohydrates and the persistent pathoglycemic peak after 3 hours serves as an added confirmation to the foregoing statement. The unexpected reduction of the blood sugar level after the initial rise is due to the effect of the low vitamin C level which stimulates insulin secretion (insulin effort phenomenon). This sudden effort apparently hinders the subsequent insulin secretion, which supposition is well based on the renewed rise of the blood sugar level which almost bears a certain resemblance to the blood sugar curves seen in diabetic patients. How far the adrenals are involved in this mechanism on account of the low vitamin C level, or are altered in their function on account of the enormous loss of sodium chloride through perspiration should be made a subject of further studies. It is, however, noteworthy to mention that McQuarrie[30] observed a more efficient carbohydrate utilization with a high sodium chloride medication and MacLean[31] gave evidence that the simultaneous sodium chloride medication in diabetic patients has reduced the insulin requirements.

CLIMATIC FACTORS

All of our patients lived largely an outdoor life whereby they were exposed to the effects of the sun during June, July, and August combined with the excessive atmospheric humidity and high temperature. No studies regarding climatic physiology of the skin has been carried out by us, but it is of interest to relate the experiences of Marchionini and Tor.[32] These authors have found in Anatolia (Turkey) during the summer months an enormous

increase of pyodermic infections of the face especially in individuals from ten to twenty years, females predominating. The authors offer proof that not only experimentally after ultraviolet ray exposure but also in individuals exposed to the sun, (1) the pH of the skin is shifted toward the alkaline side from 5.24 to 7.28); (2) in the dialysate of the skin the sugar, calcium and catalase increases and the amylase decreases.

Marchionini's[32] skin glucose findings, have not been correlated with blood sugar examinations. It should, however, be mentioned that low blood sugar figures do not exclude higher skin sugar findings in the same individual as the investigations of Urbach[33] have demonstrated. Whereas H. Laurens[34] states that "irradiation produces a lowered blood sugar and increases sugar tolerance." While no confirmation of Marchionini's findings has yet been reported, it seems a fair and logical working basis to explain the predisposition of the face for pyogenic infection of our cases. The shifting of the pH of the skin towards the alkaline side would certainly render the skin surface favorable for staphylococcus infection more especially in a skin in which the sugar concentration has been increased. The increase of catalase could indicate an increased oxidation-reduction which in our cases may explain the reduced vitamin C level of the blood. This depletion could furthermore be interpreted as a partial loss of excessive perspiration knowing that the sweat contains approximately 0.08-0.5 mg. per 100 c.c. and partly also in the later stages on account of the inflammatory purulent process knowing that the presence of oxidative substances in staphylococci especially demands an increased vitamin C metabolism (Harris).[35]

BACTERIOLOGIC FINDINGS

Cultures were made on 2 per cent glucose-agar from the superficial follicular vesicles, and also from the deeper lesions. In not a single case could we obtain *Monilia*, but in 19 cases *Staphylococcus aureus* was obtained in pure culture, whereas in 2 cases a scanty growth of *Staphylococcus albus* and *Staphylococcus citreus* were found.

DIFFERENTIAL DIAGNOSIS

Without previous knowledge of the clinical features, the first impression is suggestive of an iodide or bromide eruption. These can usually be ruled out because of a negative history of halogen ingestion. Against pustular syphilide are the acuteness of the lesions and the negative serologic finding. Furunculosis can be ruled out because of the absence of necrotic cores and because the localization is not strictly follicular. The symmetry is not a characteristic feature of either furunculosis or impetigo. Pyogenic infections following mosquito bites are frequent in China but favor more often the lower extremities. In all such instances, we see more or less impetiginous-crusted lesions developing at the site of scratching. From bacterids the differential diagnosis is usually not difficult because of the absence of an infectious focus and because of the unusual localization. From Harara (Heat disease of the face in Palestine) described by Dosztrovsky[36] this affection can be also differentiated because of the absence of phlebotomus in the Shanghai region, the

stinging of which is the cause of the disease. In its clinical appearance, syringadenitis suppurativa tropicalis is similar to varus nodulosus (Brook),[27] but the possibility of confusion is eliminated by the fact that varus nodulosus has a chronic course and long duration and also because of the absence of vesiculation and suppuration. Acne agminata (disseminated follicular lupus of Tilbury and Fox, acnitis of Barthelemy, hydradenitis destruens suppurativa of Politzer) should be mentioned not only because of the localization on the face, but also because of the long controversy whether the sweat-glands are the sites of primary involvement. The coppery colored lesions, their sluggish onset, the indolent nature of the disorder, the tuberculoid histologic changes are features not present in the disease under discussion in this paper.

DISCUSSION

Inflammatory and suppurative conditions affecting apocrine sweat glands are well known (Hydradenitis suppurativa). The only disease entity which concerns inflammation of the eccrine sweat glands, are the multiple abscesses of infants. Though the age incidence is entirely different, the clinical picture is similar with pea-to-hazelnut size, reddish, disseminated, hemispheric swellings which become fluctuating and discharge a greenish pus. The causative agent is *Staphylococcus albus* and the histopathology has a good many features in common with syringadenitis suppurativa tropicalis. In multiple abscesses of infants the onset is a periporitic pustule which penetrates into the deeper strata of the cutis and finally reaches the subcutis in the region of the sweat glands which at times are also involved in the process though often remain intact. In the disease under discussion in this paper it is also rather suggestive, but not quite obvious, that the process is a direct continuation of the invading infection through the sweat ducts. It is, however, also analogous that the infection may be carried from the vicinity to the sweat glands.

Pyogenic infections of the eccrine sweat glands of adults are not known in the temperate zone, and only certain climatic conditions and metabolic changes such as occurred in our patients would explain such an eventuality. The dilated sweat pores in prickly heat are not only a natural port of entrance for pyogenic cocci, but the irritation due to profuse perspiration renders the sudoriparous apparatus a locus minoris resistentiae. To this we have to add the diminished bacteriostatic power of the greatly diluted sweat and the possible changes brought about by the action of sunlight (increased sugar of the skin, etc.). While with large doses of vitamin C (900 to 1000 mg. daily) an appreciable improvement was noticed, smaller doses, 2 to 300 mg. were only effective when the hot weather subsided and perspiration decreased. The serum vitamin C and blood sugar level could only be increased with difficulty during the hot season, but both improved simultaneously with the onset of the cooler weather. These observations lead us to conclude that through the excessive loss of vitamin C the carbohydrate metabolism was disturbed. Though the fasting blood sugar level was rather low, the glucose tolerance test showed not only an abnormal high postcibal range, but also a delayed excretion of the sugar. The possibility of an increased glucose content of the skin, more

especially of the exposed parts, must be considered. The findings of Marchionini and Tor,[32] in respect to cases similar to our own, appear fairly reasonable because in our cases the facial localization was also a predominant feature and the covered parts seldom revealed lesions of a similar nature, though the frequent scratching, particularly of the covered regions affected by prickly heat, would greatly favor an infection. How far, besides the disturbed carbohydrate-vitamin C equilibrium, other colloidal chemical changes of the sweat gland parenchyma are involved is a matter of conjecture and beyond the scope of the present report.

TREATMENT

Treatment consisted of conservative measures, though in a few cases small incisions were made. Otherwise the local treatment depended chiefly on the stage of the disease. In case of pain, compresses with a soothing lotion was applied. In cases where the lesions were nearing breakdown, application of the following ointment was found effective:

Ichthyol	10.0 Gm.
Hydrarg. oxyd. rubr.	0.2 Gm.
Resorcin	0.4 Gm.
Vaseline	ad 20.0 Gm.

Internal medication included ascorbic acid, 200-1000 mg. daily. Neither the sulfonamide drugs (sulfathiazole or sulfapyridine) nor toxoid gave us any encouraging results.

CONCLUSIONS

1. An inflammatory and suppurative disorder of the eccrine sweat glands occurring in Chinese patients has been described under the name syringadenitis suppurativa tropicalis.

2. The disease is thought to be a complication of lichen tropicus (prickly heat).

3. The causative agents of the disease are assumed but not proved to be the *Staphylococci aureus* and *albus*.

4. Evidence is advanced that the inflammatory involvement and infection of the sweat glands is furthered by an excessive loss of vitamin C and altered carbohydrate metabolism.

5. Treatment consists in the use of appropriate topical applications and vitamin C internally.

I wish to express my appreciation to Dr. C. S. Pan, I. assistant of the Division of Dermatology, National Medical College, and to the Division of Physiological Sciences, Lester Institute for Medical Research for their kind assistance in the execution of the biochemical investigation.

THE DIFFUSION OF DYES IN ETHYLENE GLYCOL GELS

FRANCES C. BROWN, PH.D., AND E. EMMET REID, PH.D.
BALTIMORE, MD.

INTRODUCTION

SCHULEMANN[13] has pointed out the relation between the diffusion of a dye and its usefulness as a tissue stain. Regardless of whether the mechanism of staining is explained by the formation of chemical compounds between the dye and the tissue[14] or by the adsorption of the dye by the tissue,[9] the rate of penetration of the dye is a factor which must be considered in the choice of a dye as a stain. Stiles[15] has shown that conditions in dilute gels duplicate closely those present in tissues. Fautrez and Lison[4] have emphasized that while diffusion in a gel is a complicated process and should not be expected to give true values of the dimensions of the diffusing particle, nevertheless diffusion in tissues and in gels are similar processes and are controlled by the same factors. Accordingly, the diffusion of dyes in gels should throw some light on the usefulness of dyes as stains.

The diffusion of certain acid and basic dyes in ethylene glycol gels has been measured. Among the acid dyes investigated were: orange II, mercurochrome, metanil yellow, congo red, and pontamine blue BBF. Chrysoidine Y was chosen as a representative of the basic dyes. Diffusion took place in 5 per cent gelatin gels of 80 per cent buffered ethylene glycol. Ethylene glycol was chosen as the solvent, because Geschickter[7] has used it successfully in this capacity in staining tissue cultures. Its antiseptic properties are advantageous in preventing the growth of bacteria in the gel over a long period of time.

METHOD

As the buffer salts (sodium hydroxide and potassium acid phosphate) required to make gels of the desired hydrogen ion concentration are insufficiently soluble in ethylene glycol, some water had to be added. For uniformity, all solutions were made to contain 80 per cent of the glycol, the rest being water and buffer salts as required. This solution was used in the preparation of 5 per cent gelatin gels. The hydrogen ion concentration of sample solutions was measured by Dr. W. C. Harden of Hynson-Wescott-Dunning, Baltimore, Md., with the quinhydrone electrode and colorimetric standards prepared from these solutions were used as checks. Solutions of pH 5.5 and pH 7.65 were used.

The unsolidified gel was divided into two portions. One portion was poured into a 16 mm. test tube until the tube was approximately half full and allowed to solidify in the thermostat at 0° C. To the other portion was added

From the Department of Chemistry, The Johns Hopkins University, Baltimore, Md.
Received for publication, October 22, 1942.

sufficient dye to make a solution M/200 in actual dye content. The gel containing the dye was poured over the solidified clear gel of the same pH and placed in the thermostat. The dye was therefore diffusing into a medium identical in all respects, except for the presence of the dye, with that in which it was dissolved.

In the measurement of the diffusion, a photometer was used to compare the amount of light transmitted through a neutral glass filter and through the gel containing the dye solution. Two glass filters were used corresponding to different concentrations of dye, c_1 and c_2, with c_1 representing a larger concentration of dye than c_2. Daily measurements were made of the distances (d_1 and d_2) from the initial concentration of the dye, M/200, to the concentrations c_1 and c_2 measured by the photometer. In principle, this method is similar to that used by Furth[6] and by Fautrez and Lison[3] who measured the distances the dye diffused to reach a concentration which was a definite fraction of the initial concentration. Their experimental arrangements differ from those described in this paper in that they used microtechnique and measured diffusion in the solvent alone rather than in a gel.

The boundary between colored and colorless gel was also measured. Here the setting was not a photometric one; the line of demarcation between colored and clear gel as intensified by the optical instrument was measured. The symbol d_3 represents the distance of diffusion of the dye from its initial concentration, M/200, to a concentration so small that to visual observation it appears to be zero.

The laboratory measurements of two or more different samples of the same dye were plotted, using as ordinates the distances in mm. and as abscissae the time in days. A smooth curve was drawn between the points and the distances read from this curve. Fig. 1, in which the circles and triangles represent readings from two samples, illustrates the procedure followed and indicates the amount of error involved in the measurement.

RESULTS

In Table I are assembled the distances in mm. which the dyes diffused at the end of 20 days.

TABLE I

DISTANCES OF DIFFUSION IN MM. AFTER 20 DAYS

DYE	pH 5.5			pH 7.65		
	d_1	d_2	d_3	d_1	d_2	d_3
Congo Red—com.	9.2	10.6	12.85	9.45	11.0	12.4
Congo Red—purified	9.0	10.4	12.9	9.5	10.6	12.3
Pontamine Blue BBF	10.05	11.1	12.1	9.5	10.6	11.6
Orange II	13.4	14.6	16.85	14.0	15.6	17.55
Metanil Yellow	13.6	14.9	16.8	14.05	15.85	17.6
Chrysoidine Y	14.75	16.4	18.6	17.4	18.45	19.45
Mercurochrome				13.6	14.4	15.45

Conn[2] has shown that impurities present in the dye may affect its usefulness as a stain. As some of the dyes were technical samples and others carefully purified, it was important to discover whether the presence of impurities commonly found in technical samples would influence diffusion when

the actual dye content of the two samples was the same. The differences in the diffusion of a commercial sample of Congo Red and of a purified sample were found to be negligible, usually 0.2-0.3 mm. or less. This statement is based on a daily comparison of the diffusion distances of duplicate samples of the two dyes over a period of 30 days. Probably the buffer salts in the solution make the effect of additional salts present in the commercial sample negligible. These results are in agreement with the work of Valko.[17]

Table I gives the results of measurements at the two pH values investigated—one of them, pH 5.5, being very near the isoelectric point of gelatin; the other, on the alkaline side. There is little regularity in the slight differences in distance at the two pH values for the dyes with higher molecular weight; the dyes of lower molecular weight, which may be considered in true solution, show a slight but regular tendency towards more rapid diffusion in the solutions of higher pH. Mommsen[10] and Pischinger[12] in studying the effect

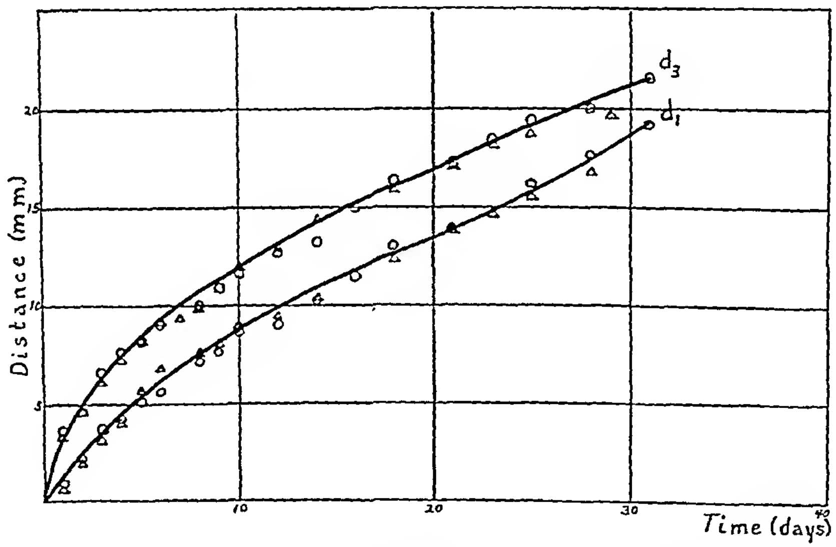

Fig. 1.—Metanil Yellow pH 5.5. Circles and triangles represent measurements on different samples.

of changing pH on the diffusion of dyes in gelatin gels have found that acid dyes diffuse more readily in less acid media and basic dyes more readily in less basic solutions. Their experiments cover a wider range of pH, especially on the acid side; our experiments fall within the pH range in which Pischinger found very slight changes in the diffusion distances.

From Stefan's development of Fick's law, the square of the amount of substance diffusing divided by the time should have a constant value if the initial concentration of the diffusing substance and the cross section in which diffusion is taking place remain unchanged. Stefan found that the same relationship should be true if the amount of substance is replaced by the distance of diffusion to a definite concentration, thus giving a constant value proportional to the diffusion constant. These relations were tested experimentally and found true, at least as a first approximation.[18]

Values of $\frac{d^2}{t}$ were calculated from the three measurements described above. It is evident from Fig. 2, in which values of $\frac{d^2}{t}$ are plotted as ordinates against corresponding values of t as abscissae, that in the case of the first two measurements, d_1 and d_2, constants were not obtained, but that with the third measurement, representing diffusion from a solution M/200 to an in-

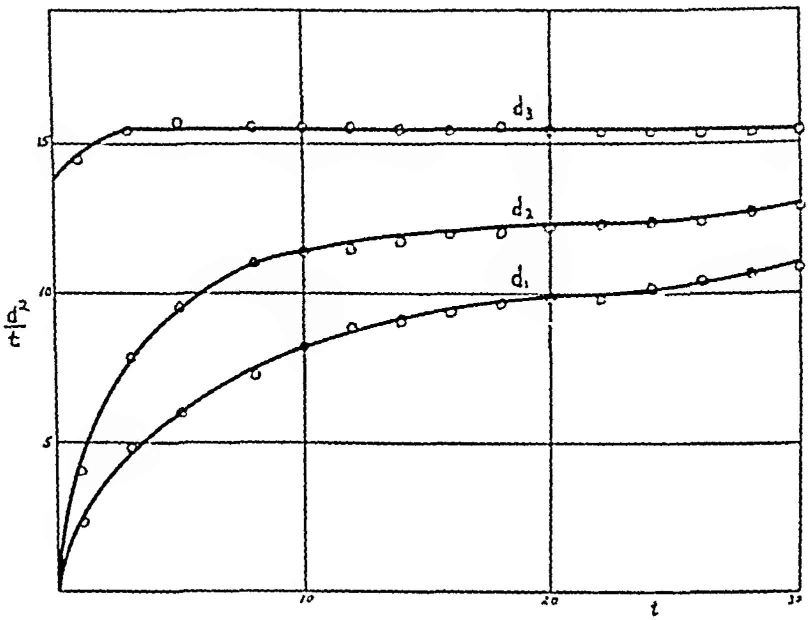

Fig. 2.—Orange II pH 7.65.

finitely dilute concentration of dye, a constant resulted. Further inspection shows that in the first two measurements, values which should be constant increase with increase in time. This suggests a logarithmic curve. Figs. 3 and 4 represent logarithmic curves for diffusion distances of typical dyes. Logarithms of the distances diffused were plotted as ordinates with logarithms of the corresponding times as abscissae. Straight lines were obtained with the first two measurements, d_1 and d_2, as well as with the third measurement, d_3. The slope of the line for d_3 is 2, giving constant values for $\frac{d^2}{t}$, but the slope of the lines for d_1 and d_2 is some fractional value between 1 and 2. When values of $\frac{d^n}{t}$ are calculated for the distances represented by d_1 and d_2, with n representing the slope as determined from the logarithmic curves, constants are obtained. In Table II, values of $\frac{d^2}{t}$ are compared with values of $\frac{d^n}{t}$ for a typical case. In Table III, values of the slope, n, and of the constant, k, from the expression, $k = \frac{d^n}{t}$, are assembled for the various dyes.

DISCUSSION

Many of the logarithmic plots show a different slope at the beginning of the process from that followed during the later stages (see Figs. 3 and 4).

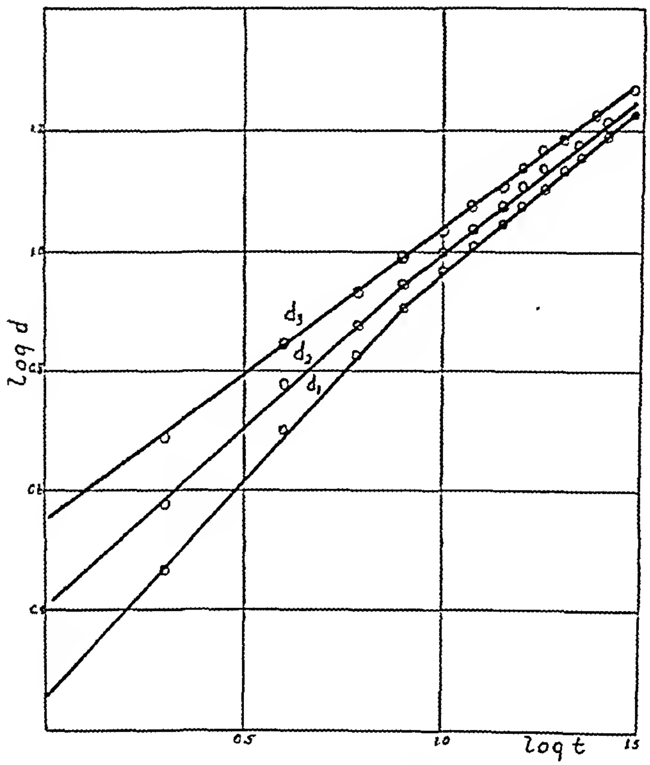

Fig. 3.—Mercurochrome pH 7.65.

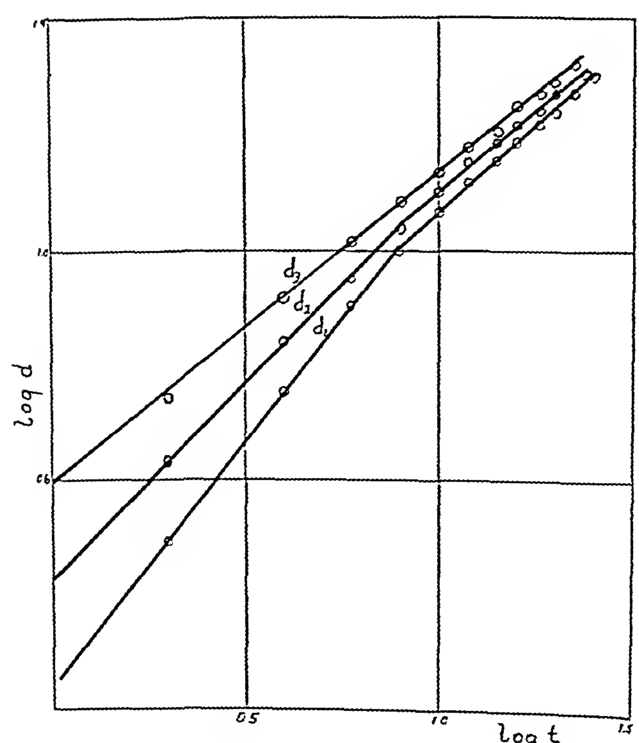

Fig. 4.—Chrysoidine pH 7.65.

This means that the advance to a definite concentration is slower and that n has a lower value in the initial stages of penetration. Similar results have been observed by Stiles[15] and by Bigwood[1] in studies of the penetration of electrolytes and of dyes. Change in structure of the gel with ageing may account for the increase in diffusion. In such cases the values of n in Table III are taken after the change in slope which occurs when diffusion has taken place for 8-10 days.

Even if the conditions upon which Fick's law is based (maintenance of the initial concentration of the diffusing substance and of the cross section in which diffusion is occurring) are observed, deviations have been noticed especially in the diffusion of a colloidal substance within a gel. One explanation[8] which has been offered is that the gel may act as a sieve, holding back larger particles (which may be caused by association of molecules or ions) and permitting the passage of smaller particles. This effect is unlikely in the present

experiments, because deviations are observed with dyes of large and of small molecular weights and because the dye in penetrating into the gel finds the same structure of gel as that in which it was dissolved. Another and more probable cause of the apparent deviations reported in this paper is adsorption of the dye on the fibers of the gelatin. Moravek[11] has measured the penetration of the lead ion into a gelatin gel containing bichromate ion and finds that the results may be expressed by a parabolic equation:

$$a = kt^{\frac{1}{n}}$$

in which a represents the depth of the diffusion layer, t the time, and k and n are constants. He ascribes his results to the affinity of the ion for the gel. It will be seen that the above equation is in agreement with the one we have used.

Friedman[5] has studied the relationship between the molecular weight of nonelectrolytes and their diffusion constants measured in gelatin. When he plots $\frac{1}{\sqrt{M}}$ against k times 10^7, the values fall near a straight line, showing that the size of the molecule influences diffusion to a large extent but that each substance does have some specific effect on the gelatin which prevents the product $k\sqrt{M}$ from being constant. The nonelectrolytes which he investigated had relatively low molecular weights. As the molecular weight and the colloidal nature of the substance increases, it is reasonable that such deviations would become more pronounced. Table IV gives the values $k_3\sqrt{M}$ for the dyes investigated. The constant k_3 was chosen because in this case diffusion was not masked by interfering factors. The symbol M represents the relative weight of the dye ion.

TABLE IV

DYE	M	$\sqrt{M}$	k_3	$k_3\sqrt{M}$
	pH 5.5			
Congo Red	650	25.5	8.19	208.8
Orange II	327	18.08	13.89	251.2
Chrysoidine Y	213	14.6	17.09	249.4
Metanil Yellow	352	18.76	10.99	206.2
	pH 7.65			
Congo Red	650	25.5	7.69	196.1
Pontamine Blue BBF	840	28.98	6.72	194.8
Mercurochrome	707	26.59	11.82	314.3
Orange II	327	18.08	15.43	279.0
Metanil Yellow	352	18.76	15.68	294.1
Chrysoidine Y	213	14.6	18.95	276.6

From a study of the above table one is impressed by the rapid diffusion of mercurochrome. Its molecular weight should indicate slow diffusion and colloidal dispersion. Yet its value for $k_3\sqrt{M}$ shows that it is more closely related to the dyes which are considered to be molecularly dispersed. Teague and Buxton[16] have measured the dialysis of various dyes and find that eosin, which has the same general structure as mercurochrome, can be dialyzed to approximately the same extent as chrysoidine although its molecular weight

is three times as large; congo red, with roughly the same molecular weight as eosin, cannot be dialyzed. These facts are in agreement with the results we have obtained.

SUMMARY

In a dye that is to be used as a stain the rate of diffusion through the tissue is important; in a dye that is depended upon as an antiseptic it is much more so. Obviously sterilization cannot extend beyond the zone of penetration.

Diffusion of dyes in a gel closely duplicates diffusion in tissues. Measurements have been made on the diffusion of various dyes into a 5 per cent gel of 80 per cent ethylene glycol buffered at pH 5.5 and pH 7.65, using a photometer to determine the distance of penetration of definite concentrations of the dye. Differences in diffusion distances of a carefully purified sample and of a commercial sample were found to be negligible when the actual dye content of the two samples was the same. When diffusion was measured to a concentration so small that to visual observation it appeared to be zero, the relationship $k = \frac{d^2}{t}$ was found to give constant values; when diffusion was measured to larger concentrations, constants were obtained for $k = \frac{d^n}{t}$, with n representing some fractional value between 1 and 2. The value of n varied with the dye and with the concentration to which diffusion was progressing; for an individual dye it was usually larger when diffusion to a more dilute concentration was measured. Adsorption of the dye on the fibers of the gelatin is believed to account for the fractional values of n. The rapid diffusion of mercurochrome, in spite of its large molecular weight, is noteworthy.

ACKNOWLEDGMENT

The authors wish to thank Mr. Fletcher B. Holmes and Dr. E. M. Hitch of the E. I. duPont Co., Wilmington, Del., and the late Mr. W. C. Holmes of the Color Laboratory, Washington, D. C., for the samples of dyes.

They also wish to thank Dr. A. H. Pfund of the Department of Physics of the Johns Hopkins University for devising the instrument used in these measurements.

SEASONAL VARIATIONS IN SOME PHYSIOLOGIC VARIABLES*

M. A. WENGER, PH.D., YELLOW SPRINGS, OHIO

THROUGHOUT the psychophysiologic study of the child subjects of the Fels Institute it has become increasingly evident that the season of measurement is an important factor influencing the results. It has been shown[10] that, in general, physiologic responses for these subjects were more consistent over a twelve-month period from winter to winter than they were over a six-month period from winter to summer.

It was thought at first that the variability of the summer data might be the result of the unstable temperature which prevails in summer in the area where the measurements were made. It was discovered, however, that although there tends to be some correlation between environmental temperature in summer and response for certain of the variables measured, some subjects were showing consistent variations which were opposite in direction to that shown in the above correlations. It was postulated that true seasonal variations were demonstrated in our data.

These seasonal variations were illustrated for one variable in an article reporting our method of measuring what has been termed "autonomic balance," i.e., a quantitative estimate of the functional state of the autonomic nervous system.[11, p. 433] The autonomic scores for six children over a period of 18 months were shown. Two cases represented those individuals who have higher scores (indicative of parasympathetic predominance) in the winter than in the summer. A second group of four cases illustrated children who show higher scores in the summer than in the winter. Another set of six cases[11, p. 432] indicated that other children may show no marked variation between the two seasons.

Since that report, additional data have been collected during the summer of 1941 and the winter of 1942. The present paper presents an analysis of all the data for those variables involved in the determination of autonomic balance. Measurements of systolic and diastolic blood pressure have also been studied. Specifically, we wish to know (a) whether there are significant group differences between summer and winter measurements for these physiologic

*From the Samuel S. Fels Research Institute, Antioch College, Yellow Springs, Ohio.
Received for publication, October 22, 1942.

responses, and (b) whether individuals show consistent differences in direction of seasonal variation.

No extensive reference is made to the literature related to these problems. Earlier work on human subjects has, in most instances, involved two few cases to answer the first question. The controversinl results reported on a few cases for such variables as heart rate,[2,4] respiration rate,[5] and others,[1,4,5] may be construed as evidence that the second problem proposed above is deserving of study. Certainly the studies of Peterson,[7] Mills,[8] and Pottenger[9] attest to the importance of the weather as a factor in health and disease, and therefore in general physiologic function.

The data reported herein have been collected in a routine manner by standardized procedures already described.[10] During the winter months of January, February, and March, all of the child subjects of the Institute who are six years of age or older come to the laboratories for a full day of measurement and study. During the summer months of June, July, and August, they again visit the laboratories for periods varying from one day to two weeks. All physiologic measurements are conducted during the hours between 9 A.M. and 12 noon. All but two, salivary output and standing palmar skin conductance, are measured in the resting state. Whenever possible, the recorded datum for an individual represents the mean of a series of samples during the examination period, which lasts about forty-five minutes. The temperature of the measurement room is maintained at 74 to 76° F. during both summer and winter, and the relative humidity is maintained at approximately 40 per cent during the winter and 60 per cent during the summer. For the purposes of this paper this difference in relative humidity is regarded as being a component of the season of measurement.

THE GROUP ANALYSIS

Since the majority of the variables studied bear some relationship to age, it was necessary to eliminate this factor from the analysis. This was done by the simple technique of comparing the means of the data for two (then three) successive winters with the values for the intervening summer (then the mean of two successive summers). The midpoint for chronological age is thus identical for the groups of data compared in each analysis. The first part of Table I shows the means, standard deviations, reliability coefficients, and criteria for judging the significance of the differences between the means for the winters of 1940 and 1941 and the summer of 1940. The data are the results of ten physiologic measurements of fifty-one children ranging in age from 6 to 12 years. The second half of the table shows a similar analysis for twenty-three of those subjects for whom data were available for the summer of 1942. Here, since a smaller number of cases was involved, the standard error of the difference has been based upon the standard deviation of the differences themselves as demonstrated by each subject.*

*The formula for the standard error of the difference between means used in the first analysis is that illustrated by Peters and Van Voorhis[11] as No. 92. For the second analysis, see their formula No. 95. The correlations employed in the first analysis are those obtained for the winter and summer data of 1940. In the second analysis (23 cases) the 1942 winter data for diastolic blood pressure and palmar skin conductance were not included, because part of them were believed to be unreliable. Since one influenced the scores of pulse pressure and both affected the derived scores of autonomic balance, the 1942 winter data for these variables also were omitted from the analysis. Diastolic blood pressure, the only one of these four variables significantly related to chronological age, was corrected for the resulting age discrepancy.

TABLE I

SEASONAL DIFFERENCES BETWEEN MEANS WITH t AND P VALUES OF THE DIFFERENCES FOR TEN PHYSIOLOGIC MEASUREMENTS OF CHILDREN AGED 6 TO 12 YEARS

	N = 51									N = 23							
NO. AND VARIABLES	SUMMER 1940		WINTERS 1940 AND 1941		DIFFERENCE				SUMMERS 1940 AND 1941		WINTERS 1940, 1941 1942	M DIFFERENCES

37 Palmar Conductance (microhms)	23.3	6.8	33.5	11.0	.32	-10.2	1.53	6.67	<.01	29.0	33.8	-4.8	9.42	2.01	2.39	.03
39 Volar Conductance	14.2	8.5	14.2	6.3	.12	0.0	1.39	0.0		11.4	13.3	-1.9	5.41	1.15	1.65	.12
57 Respiration Period (seconds)	3.01	1.95	3.19	1.04	.37	-0.18	.26	0.69	.49	2.99	3.18	-0.19	.518	.110	1.73	.10
76 Systolic Blood Pressure (mm. Hg)	96.20	6.40	98.50	5.99	.70	-2.30	.67	3.43	<.01	96.48	99.48	-3.00	3.47	.740	4.05	<.01
77 Diastolic Blood Pressure	60.70	6.74	61.60	7.45	.55	-0.90	.95	0.95	.34	59.96	60.35	-0.39	5.59	1.19	0.33	.72
80 Pulse Pressure	35.50	5.96	36.50	8.26	.38	-1.00	1.14	0.88	.38	35.17	37.30	-2.13	5.20	1.11	1.92	.07
A Autonomic Balance	72.50	9.03	72.65	7.97	.57	-0.15	1.11	0.14	.88	50.78	51.65	-0.87	6.17	1.32	0.66	.52

It will be seen that both analyses agree in placing the seasonal difference in systolic blood pressure at better than the .01 level of significance. The probability is almost as remote that the difference in palmar skin conductance could have occurred by chance; and the chances are high that the seasonal change in heart period also represents a true difference. Although the level of significance for none of the other measures is as high in either analysis as .05, it is of interest that both analyses agree in the direction of the differences.

From these results the first question may be answered. The probability is great that during the summer, as compared with the winter, systolic blood pressure is lower, standing palmar skin conductance (palmar sweating) is lower, and the heart beats at a slower rate. There also is some indication that salivary output is greater, respiration rate is faster, and pulse pressure is lower. The chances are low that true differences obtain for diastolic blood pressure, volar skin conductance, dermographia persistence, or autonomic balance, although the differences found here for these four variables are in the same direction in both analyses. The small change in the estimates of autonomic balance is of particular interest, as will be made clear in the following discussion.

For convenience in interpreting the results the 1940 regression equation[12] for the estimation of autonomic function is reproduced below. This equation is used because it is believed to be more representative of autonomic function than the 1941 equation, scores on which are greatly influenced by individual deviations in heart period.

$$\overline{Nu} = .15z_{23} + .39z_{25} + .31z_{28} + .38z_{37x} + .10z_{39x} - .10z_{5} + .22z_{6}$$

In the equation, $\overline{Nu}$ signifies the estimate of autonomic balance for a given individual; z equals the individual's standard score in the trait designated by the number in subscript; and x, following trait numbers 37 and 39, indicates that these traits have been reflected so that a high standard score is the equivalent of a low raw score. The names of the traits are the same as shown in Table I. A high score derived by means of this equation is considered indicative of functional predominance of the parasympathetic branch. A homogeneous shift in all functions toward the parasympathetic end of the scale would involve a lengthened persistence of red dermographia, an increased salivary output, a slowed heart rate, decreased palmar and volar conductance or sweating, an increased respiration rate, and a heightened pulse pressure. With the exception of dermographia persistence and pulse pressure, this is the pattern of response for summer (shown in Table I). Since these two variables are not heavily weighted in the equation, it might be expected that seasonal comparisons of these scores would reveal a significant difference between summer and winter scores of autonomic balance, with the summer season effecting a shift toward the parasympathetic end of the scale. Such a shift might also be predicted from the findings of Gellhorn and Feldman,[3] who report that heat, although affecting both the vago-insulin and sympathetico-adrenal systems, has its greatest effect upon the former. Table I shows, however, that no reliable difference obtains. The next section of this report will deal further with this finding.

THE PROFILES FOR 23 INDIVIDUALS

The individual data for the 23 children who had had five consecutive measurements were analyzed in the same general manner as were the group data for 51 cases. The scores for a given subject were combined in three ways, two combinations being the mean of two adjacent winters and the intervening summer, and the third being the mean of the two summers and the intervening winter. If the summer score for a given variable was higher than the winter score *for all three combinations,* the child was scored plus (+) for that variable. If the winter score was higher than the summer score *for all three combinations,* the child was scored minus (−). If the combinations differed in direction of change, no symbol was assigned. Instances of "no change" were infrequent and, when occurring among otherwise consistent changes, were disregarded. The series of 23 profiles obtained in this manner are shown in Table II. It should be noted that four of the variables have been reflected to make their direction consistent with respect to autonomic activity.

It will be seen that the cases are grouped in four categories. Since systolic blood pressure and palmar skin conductance had shown the most significant seasonal variation, it was argued that consistent variation in either of these variables in a direction opposite to that shown by the group might be considered as of possible significance. As might be expected, the largest group, comprising nine cases, is that which shows during the summer measurements a lower systolic blood pressure *and* a lower palmar conductance. Group II contains the five subjects who manifest higher systolic blood pressure in summer. Group III comprises four children who show higher palmar conductance in summer than in winter. Group IV includes five cases concerning which the criterion data are indecisive. The criterion data are underlined in Table II.

It is of interest to note that heart rate is slower in summer for Group I, faster in summer for Group II, and inconsistent in change for Group III. Pulse pressure also shows a certain differential group consistency. In general, it appears to be decreased in summer in Group I and increased in Groups II and III. Diastolic pressure tends to show the opposite picture. Although the results are not decisive, dermographia persistence time seems shorter in summer for Groups II and III, while volar skin conductance is lower in summer for Group I. The groups are not well differentiated for the variables salivary output or respiration period.

The first seven variables of Table II are those used in the estimation of "autonomic balance." With the reflection of the skin conductance variables 37 and 39, positive signs for all variables indicate a shift toward greater parasympathetic function; conversely, negative signs indicate a shift toward functional predominance of the sympathetic system. While there is some suggestion that Group I shows a majority of positive symbols, and Groups II and III, a majority of negative signs, a more meaningful interpretation may be drawn from the last row of the table showing the direction in shift of the derived autonomic scores. Here Groups II and III are seen to contain no positive signs. Group I contains a majority of positive signs in the last row, and the data offer a ready explanation for the three negative symbols, the encircled symbols for

the heavily weighted variables of salivary output and heart rate. Perhaps these encircled symbols represent experimental artifacts or discrete functional differences apart from the total variance in autonomic function.

In terms of this latter method of differentiation these subjects might be reclassified into two groups. Six cases from Group I and two from the indeterminate Group IV comprise those individuals who show a relatively greater parasympathetic function in summer than in winter (Group +). Groups II and III and the remainder of the cases of Groups I and IV are those who manifest relatively greater sympathetic function in summer (Group −). Since the two groups are rather evenly divided, the explanation for the lack of a reliable total group seasonal variation becomes apparent. It is of further interest that the two groups differ significantly in mean winter autonomic score. The mean winter autonomic score for Group + is 69.4. The mean for Group − (omitting the one subject who shows no variation from summer to winter) is 77.5, or approximately one σ higher. Since the σ of the difference in means is only 3.14, the obtained t of 2.58 may be considered as significant at approximately the 0.04 level of probability, when only 7 degrees of freedom are allowed. Apparently the summer season tends to effect a shift toward greater parasympathetic activity in those individuals having low autonomic scores (apparent predominance of sympathetic function) in winter, and a shift toward greater sympathetic activity in those individuals demonstrating high autonomic scores (apparent predominance of parasympathetic function) in winter. The summer seasons seem, then, to have a levening effect upon autonomic function, and it seems pertinent to question whether summer might not afford more "basal" conditions for the determination of scores of autonomic balance. Scores obtained in winter might then be viewed as reflecting the reaction of the organism to a prolonged polar front. In most temperate latitudes, however, winter must remain the season of choice for such determinations, for the environmental temperatures during the summer months are not sufficiently stable to permit the collection of comparable data on a large group.

It remains to be determined whether or not this differential seasonal variation is significant in behavior and disease. The results certainly are consistent with the observations of Peterson,[8] Mills,[6] and Pottenger.[9] Furthermore, the different groupings of seasonal variations in different functions serve to re-emphasize a consideration that Peterson has stressed; namely, the necessity for considering individual differences in response to climatic changes in any study of physiologic function.

SUMMARY

This study has concerned itself with two questions: (a) Are there significant group differences between summer and winter measurements of certain physiologic responses. (b) Do individuals show consistent differences in direction of seasonal variations. Two analyses of group data have been made; one involving data obtained during two consecutive winters and the intervening summer for 51 children 6 to 12 years of age, and the other involving data obtained during an additional winter and summer for 23 of the same children. Individual profiles were shown for these 23 cases.

The two group analyses agree in finding systolic blood pressure and palmar skin conductance (palmar sweating) significantly lower during the summer measurements. The chances are high that heart period also is significantly longer in summer. Although none of the other differences found may be regarded as reliable, there is some indication that in summer as compared with winter, diastolic blood pressure and pulse pressure are lower, salivary output is greater, respiration is faster, dermographia persistence time is shorter, and volar conductance or sweating is decreased.

The analysis of individual profiles shows that the seasons consistently have different effects on different individuals for each of the variables studied. It is believed that individuals may be meaningfully classified in at least two groups in terms of scores of autonomic balance: those who manifest relatively greater parasympathetic function in summer than in winter, and those who demonstrate relatively greater sympathetic function in summer than in winter.

THE EFFECT OF CONTINUED SULFANILAMIDE INGESTION ON THE ACID-BASE EQUILIBRIUM OF THE DOG*

ALFRED H. FREE, PH.D., DONALD E. BOWMAN, PH.D., AND DEAN F. DAVIES, M.S.
CLEVELAND, OHIO

A NUMBER of studies have been made of the effect of sulfanilamide on the acid-base equilibrium of man and animals.[2-10] Some of these studies have been carried out in patients in whom complicating effects were present. Others have either employed quantities of sulfonamide outside the range that is considered therapeutically effective or have been confined to observations following single doses of the drug. The general results of these studies have indicated that in some patients and animals evidence of acidosis is present following sulfanilamide ingestion. As a result of the effects that arise from sulfanilamide, the use of alkali with the compound has been suggested and has been rather widely used.

The present report describes studies conducted with normal dogs which were given sulfanilamide either alone or accompanied by sodium citrate. The purposes of these studies were: (1) to observe the changes in the acid-base equilibrium of the blood following the ingestion of quantities of sulfanilamide sufficient to maintain therapeutic levels in the blood; (2) to determine the changes in the acid-base equilibrium of the blood produced by combinations of sodium citrate and sulfanilamide; (3) to ascertain whether the restriction of dietary salt intake would influence the effects of sulfanilamide with or without alkali; (4) to observe the effect on the acid-base equilibrium of the blood when the concentrations of sulfanilamide are maintained above therapeutic levels over a period of several days; (5) to determine the effect of single massive doses of sulfanilamide; (6) to examine the changes in urine pH during the maintenance of high levels of blood sulfanilamide.

METHODS

Adult female dogs were employed in all of the studies and were maintained on a diet of Purina dog chow except during the studies with the low salt diet. This low salt diet was similar to that employed by Nilson,[11] consisting of cracker meal, cane sugar, casein, butterfat, and lard, and having a very low content of sodium, potassium, and chlorine. Blood samples were obtained from the jugular veins with a minimum of stasis, and urine samples were obtained by catheteriza-

tion. Methods of handling the blood as well as the references to the chemical methods employed are reported elsewhere.[16] Hemoglobin determinations were carried out on whole blood by the method of Evelyn,[17] while red and white cell counts were made by conventional hematologic techniques.

CHANGES OBSERVED IN THE ACID-BASE BALANCE OF THE BLOOD

Animals Receiving a Normal Diet.—In this series of experiments the dogs were given sulfanilamide alone, sulfanilamide and sodium citrate, or sodium citrate alone while ingesting a normal diet. Three dogs were included in each group and, by shifting the animals, the same three dogs acted as subjects in each group. Approximately ten to twelve days elapsed between the end of one experiment and the beginning of the next. The routine used in these experiments was as follows: A fasting blood sample was obtained at 8:30 A.M. on the first day of the experiment, and this was subjected to a "complete analysis" which included determinations of serum pH, carbon dioxide content, chloride, inorganic phosphorus, protein, and total base and whole blood determinations of hemoglobin, sulfanilamide, and red and white cell counts. A sample of urine, obtained by catheterization, was also taken at this time and its pH determined. At 9:00 A.M. each dog received by stomach tube the indicated compound or mixture in an aqueous solution of approximately 500 c.c. The initial dose was twice as large as all the succeeding doses. For this reason the intake of the compounds in question is 33 per cent higher on the first day than on all the following days. A second dose of the drug was administered at 1:00 P.M. and a third dose, at 5:00 P.M. The total daily dose (on all except the first day) of sulfanilamide was 0.20 Gm. per kilogram of body weight, and the dose of sodium citrate was 1.0 Gm. per kilogram. Each single dose represented one third of the daily dose. An afternoon sample of blood was taken at 4:00 P.M. and submitted to "partial analysis," consisting of determinations of serum pH, carbon dioxode content, chloride, and blood sulfanilamide. An afternoon (4:00 P.M.) urine specimen was obtained by catheterization and the pH determined. On the succeeding days of the experiment the same schedule was followed and a "partial analysis" was made on the morning and afternoon blood. Cell counts and hemoglobin estimations were done each morning, and morning and afternoon urine samples were obtained by catheterization for pH estimations. On the morning of the day that the drug was discontinued a sample of blood for "complete analysis" was again obtained.

The results of this experiment are presented in the first four columns of Table I. By the nature of the experiment, the morning analysis represents the blood level at a time fifteen hours after the preceding dose of drug, whereas the afternoon analysis represents the blood level three hours after the preceding dose. During the experiment no trend of change from day to day was discernible, and consequently only the average values for the morning and afternoon samples during the experimental period are recorded. From the data presented in Table I it will be seen that considerable fluctuation in blood sulfanilamide level occurred between the morning and afternoon samples as was to be expected. On the other hand, the level of blood sulfanilamide was approximately the same after sulfanilamide and sodium citrate as after sulfanila-

mide alone. It will be seen that the serum pH was not appreciably altered from the control level by sulfanilamide, by sulfanilamide and sodium citrate, or by sodium citrate alone, and, furthermore, there were essentially no differences in the morning and afternoon samples. The serum chloride was maintained at approximately control levels in all of the present experiments. Serum bicarbonate was slightly decreased after sulfanilamide alone, but in the afternoon samples, three hours after the administration of sulfanilamide and sodium citrate or sodium citrate alone, the serum bicarbonate was increased. The hemoglobin content of the blood was not significantly altered in any of the experiments, the slight variations encountered probably being explained by the loss of the blood removed for the chemical analyses. The erythrocyte and leucocyte counts of the blood were not appreciably changed. No significant changes in total base, protein, phosphate, or undetermined acid were noted between the beginning and end of the experiment.

Animals Receiving a Low Salt Diet.—In this series of experiments, dogs were maintained on a synthetic diet quite low in chloride and total base and were given the same combinations of sulfanilamide and sodium citrate that were employed in the preceding experiments. The low salt diet was given for one week before the start of the study and was continued during the interval of eight days between experiments. Each of the three dogs under observation was shifted so that each served in each group. The routine followed in these experiments was exactly the same as that used in the above studies on the normal salt diet with the exception that no blood or urine was taken on the third and fifth days, although the administration of the drugs was the same on these days. The results of this experiment are indicated in the last four columns of Table I. It will be seen that, in general, the results of this experiment are similar to those obtained when the animals received a diet with a normal salt content. However, throughout the experiment there was a tendency to slightly greater changes in pH and bicarbonate as a result of the ingestion of sodium citrate either alone or with sulfanilamide.

Animals Receiving Sulfanilamide at Four-Hour Intervals.—In order to ascertain the effects of blood concentrations maintained somewhat above the therapeutic levels, and also in order to decrease fluctuations of blood sulfanilamide concentrations, sulfanilamide was administered six times per day at four-hour intervals. The drug was given at 9:00 A.M., 1:00 P.M., 5:00 P.M., 9:00 P.M., 1:00 A.M., and 5:00 A.M. in amounts of 0.05 Gm. per kilogram of body weight per dose. Blood samples were obtained twice each day at 8:00 A.M and 4:00 P.M. Urine samples were obtained at four-hour intervals (see below). Three dogs were studied in this way, the sulfanilamide being given for four, six, and seven days to the three animals. The analyses included blood sulfanilamide and serum pH, bicarbonate, and chloride determinations. The results of these studies are summarized in Table II. Dogs 1 and 3 did not exhibit any adverse effects from this experiment, whereas Dog 2, after the first day of the experiment, completely refused all food and vomited considerably during the period of sulfanilamide ingestion. It will be noted that the blood sulfanilamide concentration in this dog reached higher levels than in the other two dogs and a progressive increase occurred during the latter part of the experiment. At the

same time the serum chloride in this animal fell from an average control value of 110.3 meq. per liter to a minimum of 83.0 meq. the last day of the experiment. At this time the total base concentration of the serum showed a deficit of the same magnitude as the chloride decrease. However, even though this animal was severely dehydrated, there were no significant changes in the serum pH or the serum bicarbonate concentration. It will be seen that some decrease in serum pH occurred in all three dogs, although the decrease was not progressive. Dog 3 showed a somewhat greater lowering of serum pH than the other two dogs and had a minimum value of 7.32 in one of the samples. The serum bicarbonate content showed some fall in all three animals, although the change was not marked in any.

*During sulfanilamide administration.

Animals Receiving a Single Large Dose of Sulfanilamide.—In order to ascertain the effect of large quantities of sulfanilamide on the acid-base equilibrium, dogs were given a single large dose of 1.0 Gm. of sulfanilamide per kilogram of body weight. The sulfanilamide was mixed with approximately 500 c.c. of warm water and was given as an aqueous suspension. With this quantity of sulfanilamide, marked dyspnea developed in all three animals, accompanied by clonic convulsions, spasticity, extreme salivation, and loss of most reflexes. A control blood sample was obtained along with samples at one, three, six, twelve, twenty-four, and forty-eight hours after the administration of the drug. Chemical analyses of the blood included those determinations recorded in Table III. It will be observed that a maximum concentration of blood sulfanilamide was obtained in the three-hour sample, although the concentration in the six-hour sample was quite similar. The values presented in Table III indicate that there were no marked changes in the acid-base equilibrium of the blood, although all of the animals showed marked dysfunction of the central nervous system. Hemoglobin and serum protein concentrations showed elevations that were a maximum at six hours, which would indicate that there was a loss of water from the blood.

CHANGES OBSERVED IN THE URINE pH

In both the experiments with a normal diet and with the low salt diet, it was found that the pH of urine samples obtained by catheterization were acid in the morning and alkaline in the afternoon. It has been suggested that sulfanilamide has some specific effect in preventing bicarbonate reabsorption in the

kidney tubules and that this is the basis for the disturbance in the acid-base equilibrium which follows the ingestion of sulfanilamide. In the experiments with the normal diet and the low salt diet, the blood level of sulfanilamide was at the low point when the urine was acid and was considerably higher when the urine was alkaline. The urine pH was studied more closely in the animals receiving sulfanilamide at four-hour intervals. The routine followed in these experiments has been described above, and it is to be noted that urine samples were obtained by catheterization at four-hour intervals during the day and night. The urine was collected just prior to sulfanilamide administration. With two or three exceptions, the dogs did not urinate between the four-hour catheterizations, so the entire urine output was collected in this manner. The maximum and minimum values of urine pH for the three animals for each of the days that they were receiving sulfanilamide are given in Table IV. It will be observed that a considerable range of urinary pH was encountered during the

same day in all of the dogs. With but two exceptions, the maximum pH was on the alkaline side of neutrality while the minimum pH was on the acid side of neutrality. The two exceptions mentioned occurred in Dogs 1 and 3 on the first experimental day. Dog 1 on this day had a maximum pH of 8.4 and a minimum pH of 7.0, whereas Dog 3 had a maximum pH of 7.0 and a minimum pH of 5.5. The only instance in which the fluctuation in pH was less than 1.0 occurred in Dog 2 on the fifth experimental day, when the maximum pH value was 7.4 and the minimum value was 6.9.

DISCUSSION

The present studies indicate that, with continued sulfanilamide administration and the maintenance of therapeutic levels of sulfanilamide in the blood, there are no great changes in the acid-base equilibrium. The small decrease in serum bicarbonate that occurs can be prevented by the administration of sodium citrate along with the sulfanilamide. Hematologic studies in the dogs receiving either sulfanilamide alone or sulfanilamide plus sodium citrate indicate that there was no anemia or leucopenia in any of the animals.

Hartmann[6] has suggested that respiratory alkalosis develops following sulfanilamide therapy and that administration of alkali is undesirable since it would tend to accentuate the alkalosis. Hartmann furthermore suggested that chloride deprivation would result in even more marked changes when alkali was given with the sulfanilamide. The present findings in the dogs maintained on a low salt diet do not show any indication that ingestion of sulfanilamide or sulfanilamide and alkali during salt deprivation causes alkalosis, although the urinary excretion of chloride and total base was essentially zero during sulfanilamide administration.

In the experiments in which animals were given sulfanilamide every four hours, there is further evidence to indicate that sulfanilamide does not cause severe disturbance in the acid-base equilibrium, although in these experiments the average blood level was considerably above that usually sought in clinical practice. In one of the animals (Dog 2) in which a marked dehydration developed as a result of vomiting, the serum chloride and serum total base concentrations fell by approximately 30 meq. per liter; however, the serum bicarbonate and serum pH were not markedly changed. In this experiment the collection of four-hour urine samples indicated that even though relatively high and constant blood sulfanilamide levels are maintained, the urine pH will still show considerable fluctuation. Marshall, Cutting, and Emerson[3] suggested that the excretion of an alkaline urine after sulfanilamide is due to the effect of sulfanilamide in preventing a reabsorption of bicarbonate in the kidney tubules. McChesny, Sprague, and Marshall[9] also believed this to be the case. On the other hand, Höber[12] has suggested that sulfanilamide causes an alkaline urine by reason of its inactivating effect on carbonic anhydrase. From the results that are summarized in Table IV, it would appear that other factors are also involved in regulating urine pH and that the secretion of an alkaline urine will not continue even though the blood sulfanilamide is maintained at a high and constant level. The acid-base equilibrium of the blood did not suggest any basis for the variation in urinary pH.

Marshall, Cutting, and Emerson[3] reported acid-base studies in three dogs that were given large doses of sulfanilamide. The findings suggested acidosis in some of the samples, although the results were not uniform. The dogs reported in Marshall's study showed marked signs of intoxication, as did those described in the present report which were given a single large dose of sulfanilamide. However, careful study of multiple blood samples in all three of the animals of the present study did not disclose any evidence of marked acidosis, although the serum bicarbonate was somewhat decreased. The marked dysfunction of the gastrointestinal tract and respiratory system that occurs following large doses of sulfanilamide gives a basis for disturbances in the acid-base equilibrium of the blood, although in the present experiments no marked disturbances were observed.

All of the present experiments offer evidence that the administration of sodium citrate along with sulfanilamide has no contraindications and may furthermore be desirable from the standpoint of preventing the decrease in serum bicarbonate that follows sulfanilamide ingestion.

SUMMARY

1. Studies of the acid-base balance of the blood were carried out on dogs during continued ingestion of sulfanilamide in amounts sufficient to maintain therapeutic blood concentrations. Small decreases in serum bicarbonate were observed, but there was no appreciable alteration in the serum pH.

2. Administration of sodium citrate along with the sulfanilamide prevented any decrease in serum bicarbonate and did not cause the pH to vary appreciably from the normal.

3. Ingestion of a low salt diet before and during a period when sulfanilamide or sulfanilamide and sodium citrate was ingested did not give results significantly different than were obtained during ingestion of a normal diet.

4. Maintenance of blood sulfanilamide concentrations at levels above those sought therapeutically did not produce any marked changes in the acid-base equilibrium of the blood.

5. Single massive doses of sulfanilamide, sufficient to produce signs of severe intoxication, did not cause marked changes in the acid-base equilibrium of the blood but did tend to cause a loss of water from the blood.

6. The pH of urine samples obtained at four-hour intervals during the maintenance of high blood sulfanilamide levels showed marked daily fluctuations which could not be correlated with certain views expressed in the literature.

PROTEIN HYDROLYSATE IN THE REGENERATION OF SERUM PROTEIN IN THE HYPOPROTEINEMIC RAT*

David B. Sabine, B.S., and Hans R. Schmidt, M.S., Yonkers, N. Y.

Recently there have appeared reports on the regeneration of various proteins in variously depleted animals. Some of these studies have had the aim of comparing high protein diets with equivalent amounts of protein hydrolysates[1] or of determining the relative efficiency of oral and intravenous administration.[1-3] The results of these investigations have shown, *first, that* hydrolysates are at least as efficient as whole protein; e.g., in the regeneration of plasma protein in dogs rendered hypoproteinemic by restricted diet,[1] and, second, that hydrolysates are as effective intravenously as orally.[1-3]

In the normal clinical treatment of hypoproteinemic patients (e.g., postoperative care, after more or less severe depletion) it is now not uncommon (for examples see ref. 4) to supplement a regular hospital diet with some protein hydrolysate, possibly an enzymatic digest administered orally (more rarely, and with attendant danger of shock,[3] parenterally) or an acid hydrolysate (fortified, perhaps, with tryptophane and cystine) injected intravenously. Accordingly, experiments were undertaken in this laboratory to determine whether or not a normal diet supplemented by an enzymatic protein hydrolysate would be superior to an unsupplemented diet in the regeneration of serum protein in hypoproteinemic albino rats.

*From the Biochemical Research Laboratories, The Arlington Chemical Company, Yonkers, N. Y.
Received for publication, January 15, 1943.

EXPERIMENTAL

Two sets of litter mates were used in the experiments. The first group, all males, weaned four weeks after the litter was cast, was kept on a diet of Purina Checkers until almost five months old; the second group, two males and four females (segregated as to sex after weaning), were similarly treated until almost four months old.

At this point both litters were put on *Diet 6A* (Table I). This diet, designed to deplete protein reserves, was fed *ad libitum*. Litter I was kept on this diet for 39 days; Litter II for 26 days. The animals at this time were distinctly hypoproteinemic and had lost much weight (cf. Table II). Each litter was then divided into two groups. One group received Regeneration Diet I (powdered Purina Checkers, total nitrogen 4.29 per cent), and the other, Regeneration Diet II (powdered Checkers (90 per cent) to which was added 5.5 per cent of a protein hydrolysate preparation* and 4.5 per cent cornstarch, total nitrogen 4.27 per cent). This latter mixture contained 10 per cent of its nitrogen in the form of the protein hydrolysate preparation.

On the protein regeneration diets serum protein levels were followed at approximately two-week intervals for Litter I during seven months, for Litter II during 4.5 months. The animals were weighed twice each week.

Groups B on Regeneration Diet II.

*The protein hydrolysate preparation used was Aminoids, a product containing 44.5 per cent of an enzymatic digest of dried powdered beef (15.6 per cent), wheat gluten (41.6 per cent), dried skim milk (41.6 per cent), and dried brewer's bottom yeast (1.2 per cent).

Serum protein was determined by the falling drop method, using a Kagan proteinometer,[5] on serum obtained from tail slices. All determinations were made in duplicate. In Table II are presented some of the data accumulated during these experiments. Full tabulations are omitted to conserve space.

The total consumption of Regeneration Diets I and II was measured, and the average food intake per rat was calculated from these figures. These data appear in Table III.

TABLE III

TOTAL AVERAGE DAILY FOOD CONSUMPTION PER RAT DURING REGENERATION PERIOD

	GROUP A	GROUP B
Litter I	14.35 Gm. (0.615 Gm. N)	14.42 Gm. (0.66 Gm. N)
Litter II	12.88 Gm. (0.552 Gm. N)	13.12 Gm. (0.560 Gm. N)

RESULTS AND DISCUSSION

In the case of Litter I where an average weight loss of 33.5 per cent and an average decrease of 20.4 per cent in blood serum protein concentration were recorded during the protein depletion period, the animals on Regeneration Diet I (without added hydrolysate) required a significantly longer time (123 days as opposed to 100 days) to recover the weight lost. With regard to the regeneration of serum protein, no attempt was made to estimate the amount of new serum protein formed, since blood volume studies were not undertaken. Using as an index the per cent of protein in the blood serum, it will be seen that this value rose at a significantly higher rate during the first 58 days, at least, for the animals on Regeneration Diet II (containing added hydrolysare).

The animals of Litter II showed slightly more severe weight loss (35.7 per cent) and slightly less decrease in per cent of protein in blood serum (17.5 per cent) at the end of the depletion period. Here, however, the weight recovery on both diets took place much more quickly (38 and 35 days on Regeneration Diets I and II, respectively). The only explanation which can be put forth from the data at hand seems to be that although the percentage decrease in blood serum protein content was almost as high as in Litter I, the actual value attained at the end of the depletion period was significantly higher, which suggests that these animals having been less hypoproteinemic were, consequently, in better general health. Also the animals in Litter II were about one month younger than those in Litter I and may still have been in the period of normal growth. Consideration of these factors makes even more striking the fact that the percentage of protein in the blood serum increased more rapidly on Regeneration Diet II than on Diet I.

Especially significant is the response recorded in the blood serum protein levels during the first intervals in each experiment. In Litter I the increases on Diets I and II were respectively 10 per cent and 18.1 per cent during the first 15 days; the corresponding values in Litter II were 7.9 per cent and 15.9 per cent in the first 23 days.

When one considers that a prompt response to diet therapy is the prime desideratum in the treatment of hypoproteinemia, the value of adding hy-

drolyzed protein to an otherwise normal diet is rendered impressive by this result. It has already been shown by other workers that hydrolyzed protein alone seems not to have any special advantage over unhydrolyzed protein as the dietary source of nitrogen in the regeneration of blood serum protein.[3] It is evident from these experiments that the combination of both is singularly effective and can be utilized effectively in what Davis and Getzoff[6] term posthepatic and prehepatic hypoproteinemia of certain types.

When these results are considered in the light of the data in Table III, it becomes noteworthy that the increases in blood serum protein levels were achieved in both litters without significant increases in the total intake of nitrogen; i.e., the effects observed were obtained by a substitution of hydrolyzed protein for intact protein, not by addition to an otherwise adequate diet.

SUMMARY

1. Rats rendered hypoproteinemic by diet restriction were observed to recover from the protein depleted state by oral administration of a normal diet, and of a similar diet in which hydrolyzed protein was substituted for 10 per cent of the intact protein.

2. With practically equivalent total consumption on both diets, regeneration, as measured by increase in the blood serum protein level, was practically twice as rapid on the fortified diet during the first two to three weeks of the regeneration period.

The authors are indebted to R. A. Harte for assistance in the preparation of this manuscript.

LABORATORY METHODS

GENERAL

IMPROVED METHOD OF TRANSPORTATION OF MATERIAL FROM GONOCOCCAL INFECTIONS*

Lenore R. Peizer, B.A., and Gustav L. Steffen, Ph.D., New York City

The use of gonococcus cultures has been considerably hindered by the lack of simple methods of transportation of gonococcal pus specimens to the laboratory. The method most used at present is to immerse a cotton swab containing the pus into broth or some other liquid medium in a carrying tube and to send it to the laboratory within six hours from the time the material was taken from the patient. When the culture material is in transit a longer time, negative culture results are unreliable.

Comparatively few investigators (Schofield,[1] Lumiere and Chevrotier,[2] Hauptman and Philadelphy,[3] Wortman, Gronau, Deakin, and Love,[4] Conn[5]) have studied the effect of time, temperature, and medium on the viability of gonococci in gonorrheal specimens. In the present study an attempt has been made to determine the influence of time and temperature on the survival of gonococci in specimens received on swabs immersed in broth, and to obtain data for the introduction of an improved transportation medium.

Material from known positive male and female cases of gonorrhea was used. The specimens reached the laboratory fifteen to thirty minutes after being taken. In the laboratory each swab was immediately streaked on plasma hemoglobin agar[6] and returned to the broth in the carrying tube. Two series of determinations were made; one series of 171 specimens in which the material was kept in broth at room temperature (22° C), and another of 162 specimens in which the specimens were kept at refrigerator temperature (6° C.). Following the inoculation of the immediate or control culture each specimen was plated on the same kind of medium every two hours for ten hours and again at twenty hours. The plates were incubated at 37° C. in an atmosphere of 8 to 10 per cent CO_2 for forty hours immediately after inoculation.

Table I shows the results obtained from examination of the two-hourly series of plates inoculated with known gonococcal material kept in broth at room temperatures (22° C.) and at refrigerator temperature (6° C.). The readings are separated into 4 plus (4+), 3 plus (3+), 2 plus (2+), 1 plus (1+), and plus-minus (±) according to the numbers of colonies found on the *first set* of streaked plates, which were the control plates of each series. In *Table I*, 3 plus and 1 plus readings were omitted since the results were similar to those

obtained from 4 plus and plus-minus cultures respectively. In considering the results of Table I it is essential to take into account the probable error in the percentages due to the mechanical factors involved in streaking a number of plates with one swab.

Out of a total of 171 positive specimens kept in broth at room temperature for twenty hours, 95, or 52 per cent, failed to show gonococci on culture. Of the 162 refrigerator specimens, 82, or 50 per cent, failed to show gonococci on culture.

The tests just described indicate that there is a diminution in the number of gonococci in storage of the specimen in broth, and that the diminution is in ratio to the length of time in storage. When specimens are kept in broth at room temperature, the culture frequently becomes overgrown with contaminating bacteria which prevent the isolation of the gonococci. Therefore when broth is used as a transportation medium, it is necessary to reduce the time in transportation to a maximum of four hours, particularly in doubtful cases.

In a subsequent study, in which plasma hemoglobin agar plates instead of broth were used for transportation, the following method was adhered to: A set of three plates was used for each known positive case. The plates were inoculated in the clinic and sent to the laboratory without delay. One plate from each specimen was incubated immediately at 37° C. for forty hours, in an atmosphere of 8 to 10 per cent CO_2. The second plate was kept at room temperature (22° C.) for twenty to twenty-four hours, and the third plate was placed in the refrigerator (6° C.) for twenty hours. At the end of twenty to twenty-four hours the room and refrigerator plates were incubated in the same manner as the immediate plate. The results obtained from the immediate and delayed cultures are shown in Fig. 1.

By transporting material on plasma hemoglobin agar, the loss of positives at room temperature after twenty to twenty-four hours was reduced from 52 per cent loss in broth to 11 per cent on agar, and at refrigerator temperature, from 50 per cent loss in broth to 14 per cent on agar.

Although transportation on solid medium is an improvement over the broth method, the loss of 11 to 14 per cent of positives in twenty to twenty-four hours is too great. Various substances were therefore incorporated in the medium in an attempt to find one which would effect better survival of the gonococci during transportation. When cysteine monohydrochloride, which had been used by

Cohn[5] in liquid media, was added to plasma hemoglobin agar to a concentration of 0.05 to 0.03 per cent, the gonococci in the specimen on these plates remained alive in practically every instance, when stored at room temperature for twenty to twenty-four hours before incubation.

In the preparation of the cysteine medium, a sterile 10 per cent aqueous solution of cysteine monohydrochloride is added to the melted proteose peptone agar after it has been cooled to 55° C., and before phosphate, plasma, and hemoglobin are added. This precaution is taken to avoid the formation of a precipitate. Cysteine monohydrochloride is added to a concentration of 0.03 per cent. Fig. 2

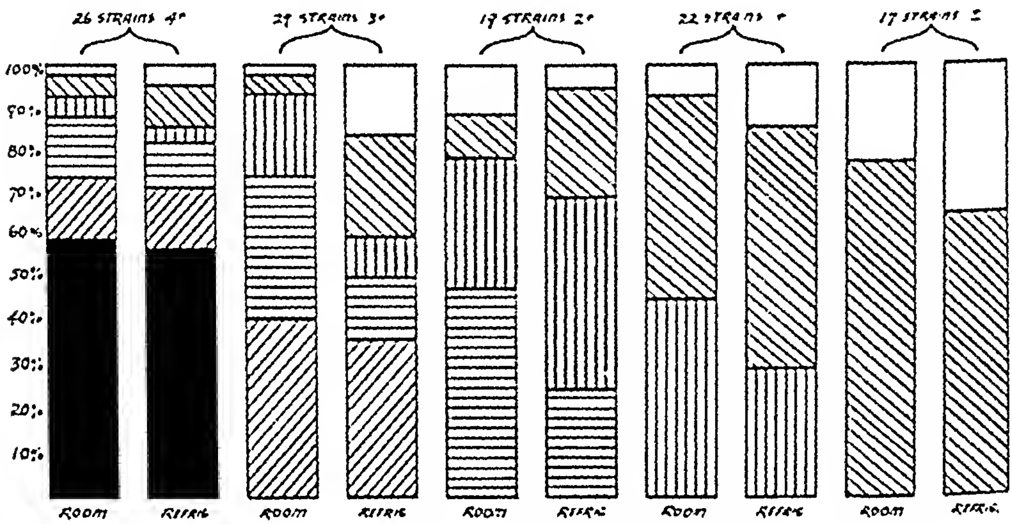

Fig. 1.—One hundred thirteen known positive strains from males streaked on horse plasma hemoglobin proteose peptone agar and left at room and refrigerator temperature for 24 hours before incubation.

Eleven strains lost at room temperature at end of 24 hours; 15 strains lost at refrigerator temperature at end of 24 hours.

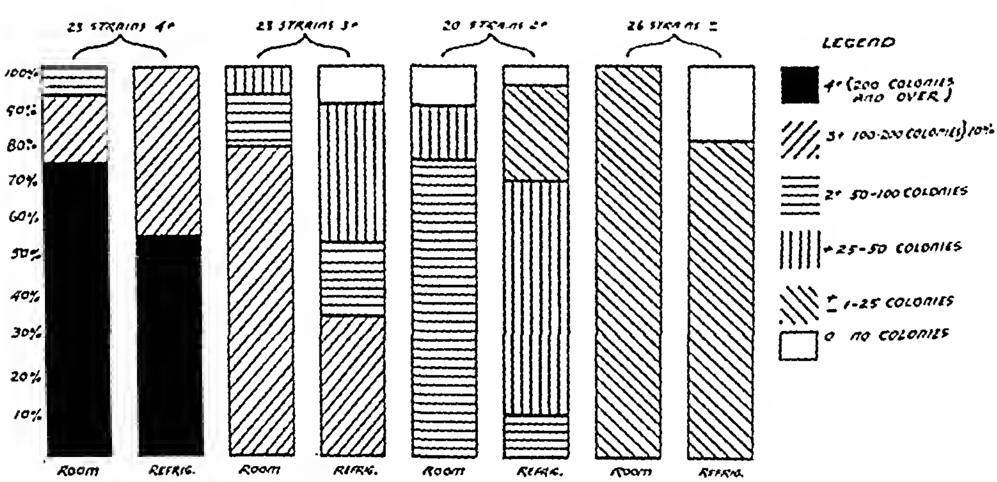

Fig. 2.—Ninety-two known positive strains from males streaked on 0.03 per cent cysteine monohydrochloride horse plasma hemoglobin agar and left at room and refrigerator temperature for 24 hours before incubation.

Eight strains lost at refrigerator temperature in 24 hours; none lost at room temperature.

shows the results on 92 known positive specimens from males, streaked on 0.03 per cent cysteine agar plates, and kept at room or refrigerator temperature for twenty to twenty-four hours. In this series no positives were lost at room temperature, and 8.7 per cent were lost at refrigerator temperature.

During this experiment l-cystine was also tested (Higginbotham[7]). This chemical inhibited the growth of gonococci when 0.1 per cent, 0.05 per cent, or 0.025 per cent was added to plasma hemoglobin agar. When 0.1 per cent was added to plasma hemoglobin agar containing veal or beef infusion as a base, it produced a luxuriant growth of gonococci. It seems that l-cystine requires a meat infusion base in order to stimulate good growth of gonococci. Because a meat infusion base is required and because the chemical dissolves only in the autoclave, l-cystine was not tested in transportation media.

The cysteine plasma hemoglobin agar was then tested as a transportation medium for general routine cultures. Each of 1,250 specimens were streaked directly on three plates, two of which contained plasma hemoglobin agar, and one, plasma hemoglobin agar with 0.03 per cent cysteine monohydrochloride. The plates without cysteine were incubated immediately as controls. The cysteine plate was kept at room temperature for twenty to twenty-four hours and then incubated in the usual manner. There were 240 positive cases, of which six control cultures were negative when the corresponding cysteine plates were positive, and five cysteine cultures negative when the corresponding control plates were positive. There was a drop in the number of colonies on cysteine plates in about 25 per cent of the positive cultures. This drop in number of colonies varies and is not in proportion to the number of colonies on the control plates. Almost all of the plus-minus cultures remained positive. The exposure of the streaked plates to out of doors winter temperatures for two to three hours did not affect the culture results.

SUMMARY

1. The streaking of gonococcal pus directly on to enriched solid medium containing 0.05 to 0.03 per cent of cysteine monohydrochloride saves 100 per cent of the positives when at room temperature up to ten hours, and about 98 per cent when left at room temperature from twenty to twenty-four hours.

2. In specimens kept in broth at 22° C. for six hours 10 per cent of positives are lost, and for ten hours 26 per cent of positives are lost. On plasma hemoglobin agar none are lost up to ten hours. When specimens are kept twenty hours at 22° C., 52 per cent of positives are lost in broth, 11 per cent on plasma hemoglobin agar, and only about 2 per cent on plasma hemoglobin agar with cysteine.

3. Transportation on solid medium is safer at 22° C. than at 6° C. Some cultures (8.7 per cent) are destroyed at refrigerator temperature when exposed to it longer than ten hours.

AN ELECTRICAL PROCEDURE FOR THE REPURIFICATION-CONCENTRATION OF ANTITOXIN*

Eugene Cardone, New York, N. Y.

When antitoxin ages, the antibody which it contains loses titer; this in all probability is a result of protein transformations which cannot be stopped. When a large decrease in antibody content occurs, the material becomes too weak for therapeutic use. Rather than discard this valuable material, it is desirable to increase its potency again by reducing its volume. The amount of total nitrogen possible per unit volume, however, is fixed by law, and therefore this reduction in bulk must be accompanied by a corresponding elimination of immunologically inert protein.

The salting-out method utilizing such salts as sodium and ammonium sulphate, first developed by Gibson,[1] and then improved upon by a host of others, is the most common method used today for purifying and increasing the titer of antitoxic plasma. Experience has shown that when this procedure is again employed in an attempt to repurify deteriorated antitoxin preparations, the losses sustained in active material are large and the increase in potency is small. In view of the fact that the englobulin, albumin, and fibrinogen fractions had been eliminated by the first purification of the antiserum, then, in the scope of this method, there is no more immunologically inert protein to be eliminated by repurification. Consequently an increase of antibody pseudoglobulin per unit volume is impossible.

An electrical process is described here which treats the antibody protein molecular aggregates in such a manner as to allow a further purification with a subsequent increase in antitoxin value per milligram of nitrogen. Furthermore, the color-carrying protein, which had been oxidized and reduced to colors varying from light brown to red, is to a great extent eliminated with the inert fraction, leaving the reprocessed material lighter in color.

The degree of increase in potency per unit of nitrogen has ranged with this process from 15 to 80 per cent. The variation is caused by the condition of the

*From the William Hallock Park Laboratory, Bureau of Laboratories, Department of Health, New York City.

Received for publication, August 3, 1942.

different lots reprocessed. Those which were old and whose protein content had become more stable did not allow as good a reconcentration as more recent material where protein transformations were more readily induced. The losses in antitoxin sustained by this process vary from less than 5 to more than 20 per cent depending again upon the condition of the material and upon the degree of reconcentration which one tries to attain.

The data in Table I give the variations in losses and in potency increase with six different lots of diphtheria antitoxin.

TABLE I

PREPARATION	ORIGINAL POTENCY IN GUINEA PIG UNITS AT 20% TOTAL SOLIDS (30.4 MG. N/GM.)	FINAL POTENCY IN GUINEA PIG UNITS AT 20% TOTAL SOLIDS (30.4 MG. N/GM.)	% LOSS IN TOTAL UNITAGE	% POTENCY INCREASE
1	3,540	4,580	6.6	29.3

4	1,630	1,970	0	20.8
5	1,120	1,740	28.7	55.3
6	1,137	1,940	0	70.6

The apparatus and procedure of the method are described here in detail because it has been found that even small variations in size of tubes, cellophane, amount of water added to the units, pH values, etc., make a decided difference in the quality of the final product.

APPARATUS NO. 4

The metal tubes are five inches long, one inch in diameter, and one thirty-second of an inch thick. They are made in the form of long, watertight thimbles. Zinc has been found to be the most efficient metal to use, because, for one reason, its ionization does not cause the serum to undergo rapid oxidation-reducing reactions accompanied by color formation.

The tubes are filled with tap water and the platinum electrodes are inserted as shown in Fig. 1.

There are two semipermeable membranes made of water-softened cellophane (Dupont, No. 600) and each contains three tube electrodes. Thus, there are three anode tubes in one membrane and three cathode tubes in the other.

The membranes are filled with tap water equal to the volume of antitoxin to be processed. The tube electrodes are immersed therein. For the support of these different units, the author has arranged a flat piece of glass with suitable holes to fit over the container, so that a metal frame firmly attached to each cellophane bag can be screwed onto it. Other holes allow the tube electrodes to be immersed in the fluid of each membrane.

The current used has been 120 volts direct current with the circuit as shown in Fig. 1. The current from a battery in conjunction with suitable resistance can be used instead, if desired. Three variable resistances are used instead of a large equivalent one for purposes of convenience only.

From 30 to 150 milliamperes are passed through the antiserum with an electromotive force of from 30 to 120 volts. This current, when used with this apparatus, has been found to cause no antibody destruction.

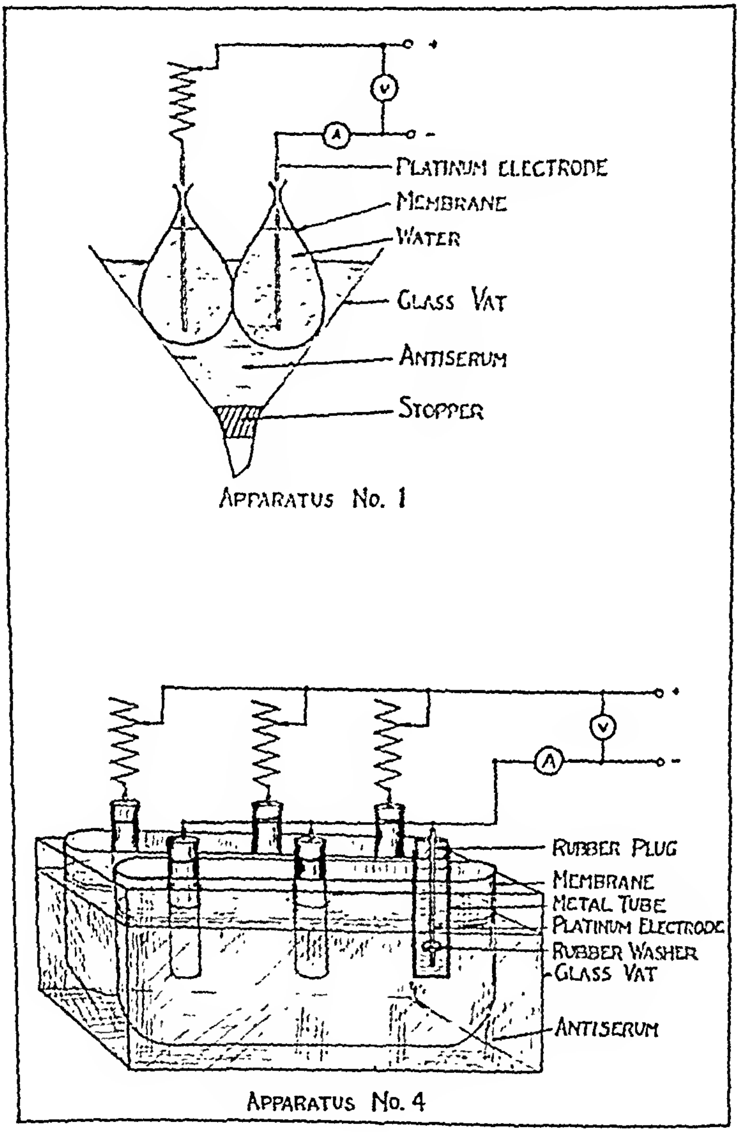

Fig. 1.

PROCEDURE

All hydrogen ion values referred to in the following description have been determined by the color comparator method. Gamma dinitrophenol and para and meta nitrophenol indicators with appropriate disc standards were used. This method has been checked with the potentiometric method and it has been found to be sufficiently accurate. It has been employed in this work because it lends itself more readily to the running of many determinations in a short time.

The antitoxin material to be processed is adjusted to a hydrogen ion value of pH 5.1 with normal acid acetic. It is dialyzed against running water until all the salts possible have been eliminated and the hydrogen ion value has increased to between pH 5.9 and pH 6.5. It is then diluted with distilled water to a nitrogen content of between 8 and 12 mg. of nitrogen per gram of material. The hydrogen ion value is again adjusted to pH 5.1 as above.

Thus prepared, the material is poured into the glass container of the apparatus, the membrane units are immersed therein, and the electric current is turned on.

When a preparation which permits visibility through it is being processed, one can immediately see stringlike oozing and settling of colloidal material all around and under the cathode membrane unit.

The material should be stirred from time to time manually unless a slow mechanical stirrer is used.

The hydrogen ion concentration must be checked often. It will be noted that as the process continues, more and more protein matter precipitates in the region of the cathode unit, accompanied by a slow but constant rise in pH value. When pH 5.9 has been attained in the mixture, the process is stopped.

It has been determined by many tests for antitoxin that the protein precipitated up to this point is mostly euglobulin. This fraction of protein is one of the immunologically inert globulin components which is precipitated between 0 and 30 per cent saturation with ammonium sulphate and whose existence has been further proved by the analysis of serum[3] with the Tiselius electrophoretic apparatus[4, 5] and the ultracentrifugal sedimentation method of Svedberg.[6] It contains no antitoxin except for a little which has been adsorbed by the precipitating proteins. This precipitate is separated from the mother liquor by filtration or centrifuging, and the precipitate is washed free of the adsorbed antitoxin by mixing it well with distilled water. The solid is sedimented or filtered again and is discarded. The washings are pooled with the filtrate or supernatant of the first separation.

In this manner the antitoxin has been repurified of an immunologically inert fraction of protein which, for the most part, would not have been present in the scope of the salting-out procedure.

The immunologically useful protein, namely, the pseudoglobulin, which remains in the clear purified material, can now be brought to a desired smaller volume by employing the following technique:

Normal sodium hydroxide is added slowly and with constant stirring to the purified colloidal solution. As the hydrogen ion concentration is reduced, more and more of the protein content precipitates out as in isoelectric precipitation. Finally at pH 7.0 to pH 7.4 all of the useful protein should be in the solid state. The precipitate is collected by filtration and the filtrate is discarded.

Normal acid acetic* is added slowly to the solid, with constant mixing, until the precipitate is in the colloidal state. The pH value of the resulting solution will be between pH 5.6 and pH 5.8. Solid sodium chloride to 1 per cent is added and the material is dialyzed against running water until only a trace of chloride

*An alkali has the same effect; however it has been found that antitoxin antibody is more tolerant to acidity than to alkalinity.

ion remains. One per cent solid sodium chloride and a suitable preservative are added after dialysis. The hydrogen ion value is set at pH 7.2 and the material is now ready for sterilization and standardization.

DISCUSSION

If according to Kruyt,[7] colloidal particles of the emulsoid type possess two factors which tend to make them stable with respect to precipitation, namely charge and hydration, and that either of these is enough to prevent aggregation of particles and flocculation of the colloid, then the apparatus as used satisfies both of these conditions and causes selective precipitation of the protein content of immune serum.

To develop the present equipment Apparatus 1 was first employed. Material processed with it showed oily, colloidal oozing and settling around and under the anode or cathode units depending on the direction of electrophoresis caused by the pH value of the antiserum.

When the process is begun with this apparatus at a neutral pH value, the settling of material at the anode unit is followed by the formation of a zone of clear fluid at the top of the serum in this region. The pH value of this clear fluid is acid and presently a hazy, ill-defined precipitate of pseudoglobulin separates out and slowly settles to the bottom layer. The clear zone then loses definition and assumes the pH value and the color of the bulk. There is no definite lasting precipitate, however, and the reaction of the serum during the process slowly becomes acid. This apparatus, therefore, although it causes protein transformations, is not enough of itself to cause aggregation of molecular particles and flocculation.

To add the necessary factor the metal jackets were added to the units, and their slow ionization completes the mechanism of the desired reaction. When antiserum at a neutral pH value is processed with this apparatus, the proteins precipitate in a thick coat on the outside surface of the anode membrane unit. When the process is begun with the serum at pH 5.1, however, the desired selective precipitation is obtained.

The hydrogen ion value of the fluids in the anode and cathode membrane units at the end of the process show the former to be between pH 6.2 and pH 6.5 while that of the latter is above pH 8.4. It has been found that an alkaline compound of the metal is formed in these units. The alkalinity produced in the anode unit, however, is transmitted to the serum as fast as it is formed by electrophoretic action. The result is a gradual rise in the pH value of the serum while that of the unit fluid itself remains constant. The cathode unit does not transmit any ion to the serum and therefore the reaction of this fluid becomes alkaline.

To demonstrate these points an alkali was added to the fluid of the anode unit, with or without metal jackets, and the pH value of the serum rose immediately. The reverse was true when an acid was added. When either acid or alkali were added to the fluid of the cathode unit no change in the pH value of the serum occurred.

That the anode metal jacket is the real functional one was shown by processing some material with a platinum electrode in the cathode unit and the

regular metal jacket in the anode unit. The serum underwent selective precipitation as usual, but the degree of reconcentration was not as good as when the complete apparatus was used. No selective precipitation occurred when the metal jacket was put in the cathode unit and the platinum electrode in the anode.

The anode tube is gradually used up during the process by the slow ionization of the metal while the outside surface of the cathode tube shows a black region, which is caused by a deposition of metal ion from the system as in electroplating.

The apparatus also causes some electrodialysis of the serum to occur making possible protein precipitation with very small quantities of metal ion.

SUMMARY

An electrical process is described which makes possible the repurification of deteriorated antitoxin material.

The apparatus is planned in a manner that allows purification and final reduction of volume by isoelectric precipitation of the proteins, thus eliminating the use of saturated salts.

The procedure is simple and it can be adapted to large-scale work.

A STUDY OF MEDIA FOR TYPHOID BLOOD CULTURES*

THOMAS C. GRUBB, PH.D., BALTIMORE, MD.

INTRODUCTION

THE isolation and identification of *Eberthella typhosa* from the blood, feces, or urine of a patient has long been recognized as the most valuable laboratory aid in the diagnosis of typhoid fever. While extensive experimentation has yielded a number of very productive types of media for the isolation of *E. typhosa* from the feces and urine, relatively little choice of media is available for the isolation of this organism from the patient's blood. The glycerol-bile-peptone medium devised by Conradi[1] in 1906 is probably the most frequently used medium for typhoid blood cultures, particularly clot cultures, at the present time. It is commonly believed, as stated by Coleman,[2] that the bile in this medium dissolves the blood clot, but in the writer's experience little if any dissolution of the clot occurs during the usual incubation period of seven to ten days at 37° C. The popular belief in this property of bile is probably based upon the misinterpretation of Conradi's original statement that the bile *prevents the formation* of a clot when whole blood is inoculated into the medium.

The routine use of clot cultures for the diagnosis of typhoid fever has become a common practice in public health laboratories during recent years, since both an agglutination test and a blood culture can be performed on the same specimen. While this practice is usually satisfactory, there is apparently an unavoidable tendency for many of the clots to become contaminated either in the taking of the blood or during transportation to the laboratory. The writer is aware of public health laboratories where as high as 50 per cent of the clots have been contaminated, especially during the warm months, despite meticulous aseptic technique after the specimens reached the laboratory. Since the majority of contaminating organisms from clot cultures in Conradi's medium are staphylococci, it would appear desirable to add some substance to the medium which would suppress the growth of staphylococci without inhibiting the multiplication of the typhoid bacillus, if present. Recently Hager and Grubb[3] reported that p-bromocinnamic acid would exhibit such a selective inhibitory action against staphylococci without affecting the growth of *E. typhosa*. Since this preliminary study suggested the utility of p-bromocinnamic acid for typhoid clot culture media, an extensive investigation was made to determine the practicability of adding this acid to Conradi's medium. The present report summarizes the results of this study. In addition, a comparative study was made with media containing sodium desoxycholate to determine whether or not this agent, suggested by Sellers[4] for blood cultures, was more or less effective than p-bromocinnamic acid in selectively inhibiting the growth of staphylococci.

*From the Department of Bacteriology, University of Maryland, School of Pharmacy.
The writer is indebted to Miss Shirley M. Glickman for assistance in this work.
Received for publication, August 5, 1942.

EXPERIMENTAL

Preliminary experiments indicated that the selective inhibitory action of p-bromocinnamic acid for staphylococci was dependent upon the concentration of the acid and the pH of Conradi's medium to which it had been added. It was found that the lower the pH of the medium, the less the amount of p-bromocinnamic acid required to suppress the growth of staphylococci. Likewise, if sufficient p-bromocinnamic acid were added at a low enough pH, a point was reached where the growth of the typhoid bacillus as well as that of the staphylococci was completely inhibited. It was therefore obvious that the proper balance of pH and concentration of p-bromocinnamic acid must be found which would inhibit the growth of staphylococci without affecting the growth of *E. typhosa.* After several trials it was found that if Conradi's medium was adjusted to pH 5.0 with p-bromocinnamic acid in a concentration of 1:5000, the medium would exhibit the desired selectivity. Table I indicates the results obtained with this combination containing 10 per cent of defibrinated rabbit's blood. Freshly isolated strains of *E. typhosa** and *Staphylococcus albus* were inoculated into the medium and plate counts in nutrient agar made immediately after inoculation and after twenty-four hours' incubation at 37° C.

It is evident from the data shown in Table I that there is a definite bactericidal action on both strains of staphylococci, while the multiplication of the typhoid bacillus was apparently unaffected. It is to be noted that an extremely large inoculum was used in the above experiment.

TABLE I

SELECTIVE BACTERICIDAL ACTION OF P-BROMOCINNAMIC ACID (1:5000) IN CONRADI'S MEDIUM (pH 5.0) CONTAINING 10 PER CENT BLOOD

ORGANISM	TOTAL PLATE COUNT PER C.C. OF MEDIUM	
	IMMEDIATELY AFTER INOCULATION	24 HOURS' INCUBATION AT 37° C.
E. typhosa No. 1	940,000	51,000,000
E. typhosa No. 2	400,000	34,000,000
S. albus No. 1	21,000	40
S. albus No. 2	100,000	23,000
Control Medium Without P.Bromocinnamic Acid		
E. typhosa No. 1	1,060,000	20,000,000
E. typhosa No. 2	920,000	22,000,000
S. albus No. 1	570,000	46,000,000
S. albus No. 2	860,000	64,000,000

In order to determine the effect of various concentrations of blood upon the inhibitory action of p-bromocinnamic acid, defibrinated rabbit's blood was added to Conradi's medium in amounts varying from 1 to 30 per cent. When the concentration of blood exceeded 15 per cent, there was a definite reduction in the inhibitory activity of p-bromocinnamic acid, which became more pronounced in the higher concentrations of blood. It is difficult to estimate how much blood or serum is liberated in the usual clot culture, but for the purposes of experi-

*Freshly isolated strains of *E. typhosa* from blood cultures were obtained through the courtesy of Dr. C. A. Perry, Director, Bureau of Bacteriology, Maryland State Department of Health.

mentation a concentration of 10 per cent has been selected as representing an average amount and has been employed throughout the experiments reported here.

While a concentration of 1:5000 p-bromocinnamic acid apparently had no inhibitory effect upon the growth of *E. typhosa* when a very large inoculum was used (400,000 to 940,000 per c.c. as shown in Table I), it was deemed advisable to determine the effect of this concentration upon a small inoculum. The number of organisms which should be used as an inoculum to simulate the number found in the blood stream of a typhoid patient is probably very small. Müller and Gröff[5] made plate counts from blood cultures of 256 typhoid cases and found that 82.2 per cent of the cultures contained between 1 and 50 organisms per c.c. of blood. Plate counts made on the blood of 43 patients in the University of Maryland Hospital showed between 1 and 63 typhoid bacilli per c.c. of blood; however, when a number of hours intervenes between the taking of the blood and the laboratory examination, such as occurs when specimens are sent through the mail to public health laboratories, it is difficult to predict what degree of multiplication will take place. For experimental purposes, inocula containing from 10 to 20 organisms were employed, and this small number of typhoid bacilli was markedly inhibited in Conradi's medium adjusted to pH 5.2 and containing 1:5000 p-bromocinnamic acid.

Since Sellers[1] had reported the use of desoxycholate broth for the culture of clots from suspected cases of typhoid fever, it was considered of interest to determine how this medium compared with the p-bromocinnamic acid medium described above. The formula for this medium, kindly supplied by Harris,[6] is as follows: peptone, 1 per cent; Na_2HPO_4, 0.35 per cent; sodium desoxycholate, 0.1 per cent. The hydrogen-ion concentration of the medium is adjusted to pH 7.0 to 7.2 before autoclaving at 15 pounds' pressure for fifteen minutes. Small inocula (10 to 25 organisms) of two recently isolated strains of staphylococci and *E. typhosa* were inoculated into the p-bromocinnamic acid and the desoxycholate media, and incubated 24 hours at 37° C. when plate counts in nutrient agar were made. The results of this experiment, which was repeated several times, are given in Table II.

It is evident from the data in Table II that while p-bromocinnamic acid is bactericidal for staphylococci, it is also markedly inhibitory for typhoid bacilli when a small inoculum is employed. On the other hand, the desoxycholate broth completely suppressed the growth of staphylococci while allowing considerable growth of *E. typhosa*. These data indicate clearly that sodium desoxycholate is a much more effective substance than p-bromocinnamic acid for the selective inhibitory action on staphylococci in typhoid blood cultures.

To determine what effect variations in the pH of the medium and concentration of sodium desoxycholate would have upon the selective inhibitory action of the desoxycholate broth, various portions were prepared containing from 0.05 per cent to 0.3 per cent sodium desoxycholate with the hydrogen-ion concentration of the broth ranging from pH 6.0 to 8.0. These portions, containing 10 per cent defibrinated rabbit's blood, were inoculated with approximately 10 staphylococci or typhoid bacilli per 5 c.c. of medium and incubated

twenty-four hours at 37° C. Each portion was then plated in nutrient agar to determine the total number of organisms present. The results of this experiment are shown in Table III.

TABLE II

COMPARISON OF THE BACTERICIDAL ACTION OF P-BROMOCINNAMIC ACID IN CONRADI'S MEDIUM WITH THAT OF DESOXYCHOLATE BROTH

MEDIUM	TOTAL PLATE COUNT PER C.C. OF MEDIUM AFTER 24 HOURS' INCUBATION AT 37° C.			
	ORGANISM		ORGANISM	
p-bromocinnamic acid (1:5000)	*S. albus* No. 1	0	*E. typhosa* No. 1	73
	S. albus No. 2	0	*E. typhosa* No. 2	1,070
Sodium desoxycholate (1:1000)	*S. albus* No. 1	0	*E. typhosa* No. 1	500,000
	S. albus No. 2	0	*E. typhosa* No. 2	700,000

TABLE III

EFFECT OF VARIOUS CONCENTRATIONS OF SODIUM DESOXYCHOLATE AND PH OF THE MEDIUM ON THE GROWTH OF *E. Typhosa* AND *S. Albus* IN DESOXYCHOLATE BROTH

ORGANISM	pH	TOTAL PLATE COUNT PER C.C. OF MEDIUM AFTER 24 HOURS' INCUBATION AT 37° C.			
		0.05%*	0.1%	0.2%	0.3%
S. albus No. 1	6.0	0	0	0	0
	7.0	0	0	0	0
	8.0	0	0	0	0
E. typhosa No. 1	6.0	22,100,000	48,000,000	25,000,000	28,000,000
	7.0	30,000,000	69,000,000	35,000,000	71,000,000
	8.0	11,000,000	24,400,000	71,000,000	34,000,000

*Concentration of sodium desoxycholate.

The data in Table III show the complete inhibition of growth of staphylococci while *E. typhosa* grew luxuriantly. Nutrient broth control tubes (pH 7.0) containing 10 per cent blood inoculated at the same time and incubated in a similar manner contained 153,000,000 staphylococci and 130,000,000 typhoid bacilli per c.c. of the culture. Thus while the sodium desoxycholate in the concentrations employed in this experiment has some inhibitory action on *E. typhosa*, it is probably insignificant so far as the practical usefulness of the medium is concerned. While the number of typhoid bacilli developing in the various concentrations of sodium desoxycholate at different pH values varied from 11,000,000 to 71,000,000 per c.c., there is no apparent relationship between the two variables and the number of organisms developing. It is believed that for practical purposes the desoxycholate broth will exhibit adequate selective inhibitory action in any of the combinations of pH and in the concentration of sodium desoxycholate shown in Table III. The fact that neither the concentration of the sodium desoxycholate nor the pH of the medium requires critical adjustment increases the practical usefulness of the medium.

Since it was found that the inhibitory action of p-bromocinnamic acid on staphylococci was nullified to a considerable extent by concentrations of blood exceeding 15 per cent, it was considered of practical importance to determine whether or not blood had a similar effect in the desoxycholate medium. Defibrinated rabbit's blood in concentrations ranging from 1 to 30 per cent was added

to desoxycholate broth containing 0.1 per cent sodium desoxycholate and adjusted to pH 7.0. Small inocula (100 to 200 organisms) of *E. typhosa* and *S. albus* were inoculated into the broth containing various amounts of blood and incubated at 37° C. for twenty-four hours when plate counts in nutrient agar were made. Even in the media containing 30 per cent blood there was no reduction in the inhibitory action of sodium desoxycholate on staphylococci, while in the media containing only 1 per cent blood, there was no inhibitory action on the growth of typhoid bacilli. This experiment indicates that variations in the concentration of blood, within the probable limits found under practical conditions, do not affect the selective inhibitory action of sodium desoxycholate in the medium described.

While sodium desoxycholate was shown to display an effective bactericidal action on staphylococci in previously described experiments where small inocula were used, it appeared advisable to determine the inhibitory action of this substance against a large inoculum, since considerable multiplication of contaminating staphylococci may occur when the blood specimen is sent through the mail to the diagnostic laboratory. In order to study this problem, 0.1 per cent desoxycholate broth adjusted to pH 7.0 and containing 10 per cent blood was prepared. Varying numbers of staphylococci were inoculated into tubes containing 5 c.c. of the medium and incubated twenty-four hours at 37° C. when plate counts were made to determine the number of surviving organisms. The results of this experiment are shown in Table IV.

TABLE IV

ACTION OF DESOXYCHOLATE BROTH UPON VARIOUS NUMBERS OF *Staphylococcus albus*

NUMBER OF ORGANISMS INOCULATED INTO 5 C.C. OF MEDIA	NUMBER OF ORGANISMS VIABLE AFTER 24 HOURS' INCUBATION AT 37° C.
12,800,000	4,000
1,280,000	3,050
128,000	450
12,800	50
1,280	0
128	0

This experiment demonstrated that sodium desoxycholate has a very effective bactericidal action against large numbers of staphylococci; and even though some of these organisms do survive over a 24-hour period, the number of surviving organisms is insignificant compared to the number of typhoid bacilli which grow during this period under the same conditions (see Table III).

DISCUSSION

The experiments described in this report indicate that while p-bromocinnamic acid shows a selective inhibitory action against staphylococci when the concentration of the acid and the pH of the medium are properly adjusted, this selective activity probably cannot be utilized in a medium for the culture of blood clots because small numbers of typhoid bacilli are inhibited. On the other hand, a simple broth containing from 0.05 to 0.3 per cent sodium desoxycholate and adjusted to pH 6.0 to 8.0, shows a remarkably clear-cut bactericidal

action against staphylococci without a significant degree of inhibition for the typhoid bacillus. This selective activity is manifest despite wide variations in the amount of blood present and despite an enormous inoculum of staphylococci. These experiments suggest that a desoxycholate broth, similar to that described, should prove very helpful to laboratories where difficulty is experienced in avoiding or eliminating contamination of blood clot cultures with staphylococci.

SUMMARY

1. A study was made of the utility of p-bromocinnamic acid incorporated in Conradi's medium for the purpose of inhibiting the growth of contaminating staphylococci. Although p-bromocinnamic acid showed a selective inhibitory action against staphylococci, it also inhibited small numbers of typhoid bacilli and therefore was not considered of practical value for the culture of blood clots from suspected cases of typhoid fever.

2. A simple broth containing sodium desoxycholate displayed an effective inhibitory action against staphylococci without an appreciable bacteriostatic effect upon the typhoid bacillus. The broth does not require critical adjustment of pH or concentration of sodium desoxycholate, and is effective in various concentrations of blood against large numbers of staphylococci.

MICROSCOPIC OBSERVATION OF COLLODION PARTICLES AS INDICATORS OF TYPE-SPECIFIC PNEUMOCOCCIC IMMUNE REACTIONS

MARTIN BURGER, M.SC.
NEW YORK, N. Y.

THE object of this study was to detect the presence of minute amounts of pneumococcal soluble-specific substances (S.S.S.) in vitro. A sensitive microscopic technique was developed which was compared with a slightly modified method of Goodner's[1] and with the ordinary precipitation tests.

In 1932 Freund[2] demonstrated that anthrax soluble carbohydrate hapten was adsorbed by colladion particles; for on adding anthrax-immune serum to the hapten-sensitized particles, agglutination resulted. The agglutination was observed best in a hanging-drop preparation, but the titers of the reagents were not reported.

Experimental.—Collodion particles were prepared according to the method of Cannon and Marshall[3] except that double-distilled rather than triple-distilled water was used, as recommended by Eisler.[4] The particles obtained from 75 ml. of 5 per cent acetone stock solution, after aspirating, washing, and centrifuging, were suspended in 100 ml. of double-distilled water and used without further diluting.

Into agglutination tubes was added 0.02 ml. of collodion suspension followed by 0.1 ml. of S.S.S. dilution. The latter was made up in physiologic saline. After thorough mixing, the tubes were allowed to stand for from five to ten minutes at room temperature, then 0.1 ml. of antiserum added. The contents were mixed again, capped with rubber stoppers, and placed in the refrigerator overnight. With each test, a serum control (0.02 ml. collodion suspension plus 0.1 ml. antiserum) and an S.S.S. control (0.02 ml. collodion suspension plus 0.1 ml. S.S.S. dilution) were made. Another set of tubes containing the same amounts of reagents were simultaneously made up for the so-called "collodion-fixation test" of Goodner.[1] A third set without collodion particles constituted the ordinary precipitation test.

Microscopic Technique.—A drop of the collodion plus antigen (S.S.S.) plus antiserum suspension is placed on a plain glass slide. Next to it is placed a drop of the serum plus collodion control and next to this, a drop of the antigen plus collodion control. Each drop is covered with a coverglass and examined under the oil immersion lens. It is desirable to flip each tube gently about ten times just before withdrawing the drop of suspension. In the mounts containing the higher concentrations of S.S.S., one sees definite amorphous masses containing enmeshed collodion particles. These are designated 4 plus and 3 plus in Table I. A 2 plus reading signifies the presence of relatively large clumps

From William Hallock Park Laboratories, New York City Department of Health, Bureau of Laboratories, New York, N. Y.
Received for publication, Sept. 2, 1942.

of collodion particles without a trace of the amorphous precipitate. A plus reading means that the majority of the fields examined contain more clumps (small in size) and fewer single particles as compared with the controls. With one exception, all the serum and antigen controls thus far examined contained some small collodion clumps and many single particles; that is, the dispersion was good. The exception, a concentrated horse serum plus collodion control, contained large clumps of particles and was similar to a 2 plus reading.

The results of a typical comparative test are shown in Table I.

†Coarse particles, not easily broken up on vigorous flipping.

SUMMARY

A microscopic method of observing collodion particle agglutination is described. In higher dilutions of pneumococcus S.S.S., the method gives positive results, while negative results are obtained by macroscopic examination either of the same tests or of ordinary precipitation tests.

CHEMICAL

A METHOD AND APPARATUS FOR SHELL FREEZING AND RAPID DRYING OF PLASMA AND OTHER PRODUCTS FROM THE FROZEN STATE BY LOW TEMPERATURE WATER VAPOR CONDENSATION IN VACUO*

MAX M. STRUMIA, M.D., AND JOHN J. MCGRAW, M.D., BRYN MAWR, PA.

INTRODUCTION

HUMAN plasma transfusion is now generally accepted as an important therapeutic agent in the treatment of shock, associated with trauma, hemorrhage, or burns as well as of hypoproteinemias, hypoprothrombinemias, and of some hemorrhagic conditions. Preservation of plasma in the frozen state has been recommended as the safest, most efficient, and practical method for the average hospital.[1] The establishment of "plasma banks" in which the plasma is maintained frozen will allow most institutions to meet the routine or emergency needs of the communities which they serve in almost all instances. This is true of the present national emergency. "Banks" of frozen plasma are being established in many hospitals throughout the country in view of the increasing danger of industrial accidents associated with large scale production and the possibility of enemy action within the United States. Large stores of dried plasma are being prepared for use with the Armed Forces beyond the limits of the continental United States. Conditions do exist, and further situations may arise, in which a certain amount of dried plasma is needed for civilian use.

Very few hospitals at present are in a position to offer the use of dried plasma for their patients, except through outright purchase of the material. This situation in effect denies the patient the opportunity of availing himself of the use of friends and relatives as volunteer donors. In a previous publication[1b] it has been pointed out that this difficulty could be overcome if a group of hospitals would cooperate in the preparation of dried plasma. Since the preservation of plasma in the dried state is only seldom essential in the ordinary civilian practice, a single large institution could easily dry a sufficient quantity to meet the need of several others on a cooperative nonprofit basis. Almost any hospital can easily maintain its own store of frozen plasma, which would be supplemented by a small amount of the dried material supplied by the drying center. Under favorable conditions, a large institution may assume the responsibility for supplying plasma in both frozen and dried states for neighboring institutions.

*From the Bryn Mawr Hospital, Bryn Mawr, Pa.

Received for publication, January 11, 1943.

A plan of this nature has been operating successfully for over eighteen months in the Cincinnati General Hospital under Dr. Hoxworth.[16] The service supplies the needs of fourteen hospitals with a total bed capacity of 4,235. A state-wide plasma service is being organized by Dr. James of the University of Vermont Medical College.[17]

The purpose of this paper is to describe a method and an apparatus for the drying of plasma from the frozen state by low temperature water vapor condensation in vacuo suited for the plan just mentioned.

While the essential details of construction are given, no attempt is made to describe the apparatus minutely. Likewise, no attempt is made to give details of performance under all conditions of temperature, vacuum, etc., nor to justify many statements made concerning newer methods employed, such as the shell freezing at relatively higher temperatures, etc.

These phases of the work will be covered in subsequent papers.

A DISCUSSION OF PREVIOUS APPARATUS AND BASIC PRINCIPLES INVOLVED

Up to the present, all of the various apparatus described for the desiccation of plasma from the frozen state have been either too small for practical use or too expensive if large enough to serve the purpose. Some apparatus, although inexpensive to purchase, have proved a financial burden because of the operating expense and the need of much technical supervision. Most of these apparatus have been recently critically reviewed by Harkins.[2]

Of all the methods in use, we feel that desiccation from the frozen state in the final container is preferred, because this method provides for maximal preservation of all elements of the plasma, maximum solubility, minimal opportunity for contamination during the process of drying, and regeneration with 0.1 per cent citric acid prior to use.

It is important to note that the pH of plasma dried from the frozen state and restored with distilled water varies from 8.2 to 9.3. The same material regenerated with 0.1 per cent citric acid will have a pH varying from 7.4 to 7.8.[15]

The use of low temperatures for the condensation of the water vapor removed from the frozen plasma is preferred because it is efficient and relatively inexpensive. In the apparatus to be described here, the same source of low temperature is used for both prefreezing of the plasma in shell form and for water vapor condensation during the process of drying. The source of low temperatures is obtained by expansion of compressed Freon-12 gas in evaporator coils or plates. It is based on the fundamental principles employed by the early workers in this field.[3] In addition, the successful operation of this apparatus involves five important facts, which previously had not been generally accepted or taken advantage of:

1. The temperature of freezing of plasma has little or no practical effect, within the experimental limits (minus 12 to minus 72° C.), on the quality of the final product.

2. The temperature at which water vapor condensation is carried out is not critical, within the experimental limits (minus 30° to minus 72° C.), provided that the rate of evaporation at any time during the operation is sufficiently

rapid to avoid thawing of the frozen plasma. This is readily accomplished by using a condenser possessing a condensing surface sufficiently large and by taking advantage of certain details of construction of the condensing chamber pointed out later.

3. The temperature of the condensing coil during the period of maximal sublimation may rise somewhat above the minimum mentioned (minus 30° C.) without adversely affecting the process, provided that during the last few hours of the process the temperature is maintained between minus 30° C. and minus 35° C. or below.

4. The temperature of the water jacket heating the plasma may be raised, during a portion of the process, to relatively high temperatures (80° C.) without impairment of any of the essential qualities of the resulting product, but with considerable shortening of the time of drying as compared with apparatus without proper thermic control.

5. The temperature of the plasma itself may be raised to relatively high temperatures (75° to 80° C.) without deterioration, provided that the amount of moisture present is relatively low. This occurs in the last few hours of the process.

The demonstration of these facts has allowed the development of an efficient, practical apparatus, which will fit the program of plasma drying mentioned above. The use of very low temperatures (about minus 70° C.), which has been emphasized for both prefreezing and drying, has been one of the main factors in the almost prohibitive cost of other apparatus. Several types of inexpensive standard refrigerating machines on the market are capable of producing constant temperatures in the nature of minus 40° C. and thus allow the construction of a satisfactory apparatus at a low cost.

In the construction of the apparatus, the following practical points were kept in mind:

1. The product obtained should, when regenerated with solvent, be as nearly as possible identical with the original material. The apparatus and process employed, therefore, must allow no degeneration to occur during the process of drying. The plasma obtained with the apparatus here described in all ways complies with the regulations set forth by the National Institute of Health.

2. The apparatus must be so designed and the operation so controlled as to be constant, thus insuring a uniform product. It must be remembered that drying from the frozen state may be achieved in a great many ways and with much simpler apparatus. However, mechanical controls of temperature, recording devices for temperature and pressure, and other refinements of construction play an important role in insuring a uniformly good product.

3. The apparatus must be simple and economical in its operation, as much as possible automatic, so as to need a minimum of supervision once under way. It should provide facilities for shell freezing as well as for drying. To achieve simplicity and economy of operation, the apparatus, paradoxically, has to be relatively expensive and complicated.

It has been pointed out that drying from the frozen state may be achieved with a simple and inexpensive apparatus.[4] Such an apparatus, however, has a

limited capacity, requires much technical supervision, and is high in operating cost. The apparatus to be described here was so designed as to have a capacity large enough for the need of several hospitals. It requires very little attention during the operation, and the operating expense is negligible.

Thus the standard apparatus here described freezes and dries 24 units of citrated plasma of 300 c.c. each daily (7.2 liters), or 8,760 yearly (2,628 liters). The total cost of electric energy for shell freezing and drying is well under $.02 per unit, or less than $175.00 yearly. For the same operation, if carbon dioxide ice is employed, the yearly cost of refrigeration would be about $3,006.00, or considerably more than the entire cost of purchase of the apparatus.*

In order to evaluate properly the construction and performance of this apparatus, it is necessary to review the general basic principles of drying biologic substances. The Bordas and d'Arsonval apparatus,[3b] as reconstructed by us, demonstrates these basic principles in a simple form (Fig. 1). It consists of two glass flasks connected by a T-tube. One flask (A) contains a thin layer of material to be dried. The other flask (B) is the condenser. The T-tube is connected to a vacuum pump by means of a rubber tube (C), which may be closed by a stout pinch clamp. The glass tube connecting the two flasks must be of sufficient size to allow free passage of water vapor from A to B. Flask A is immersed in water kept at plus 15° C., and Flask B, acting as condenser, is cooled by immersion in carbon dioxide ice-alcohol mixture, maintaining a temperature of about minus 70° C.

Containers A and B are stout-walled Erlenmeyer flasks of about 500 c.c. capacity. Under these conditions, when 30 c.c. of plasma are introduced in Flask A, "snap" freezing, from the heat loss due to rapid evaporation, occurs in about five minutes after starting of the vacuum pump; thereafter, drying proceeds by sublimation of water from the frozen state. The water vapor is condensed on the cold walls of Flask B as fast as it is formed; thus it is not allowed to mix with the oil of the pump, which would rapidly reduce the efficiency of the pump. The dried plasma thus obtained appears in the form of irregular scales, has a residual moisture of less than 1 per cent, and is readily soluble.

Practically all of the various types of apparatus in general use for drying under a vacuum are based upon variations in the method of condensing the water vapor.

In the original apparatus used by Bordas and d'Arsonval, liquid air or carbon dioxide snow-acetone was used as refrigerating agent.

Vansteenherghe[3a] used sulfuric acid to absorb the water vapor instead of low temperature; Reichel[5] and Flosdorf and Mudd[6] used an apparatus similar to that of Bordas and d'Arsonval and CO_2 ice as the refrigerating agent for the "lyophile" process; later Flosdorf and Mudd[7] returned to the use of a chemical dehydrating agent and employed calcium sulfate in their "cryochem process"; Hill and Pfeiffer[8] used silica gel in their "adtevac" process.

Elser[3f] was the first to report the use of coils refrigerated by the expansion of compressed Freon-12 gas for condensation of water vapor. In actual opera-

*The cost of CO_2 ice is computed at $.03 per pound, the lowest prevailing price when purchased in large quantities. The amount of dry ice required is based upon our experience with a similar apparatus.[12]

tion, minus 34° C. to minus 36° C. were the lowest temperatures attained. Elser pointed out that the loss in efficiency from the change of the condenser temperature from minus 70° C. to minus 32° C. was relatively slight, roughly 5 per cent.

The failure of the mechanical refrigeration system of Elser has generally been laid to the too small differential in temperature between the substance being dried and the condensing surface. This is not confirmed by our findings, since satisfactory drying with a residual moisture of less than 1 per cent has been obtained with a maximal differential temperature of only 65° C.

We have already pointed out that the temperature of prefreezing is not critical within the experimental limits (minus 12° C. to minus 72° C.). With the apparatus here described, prefreezing and drying are carried out at much higher, and therefore much more convenient and economical, temperatures than generally employed without essential loss of quality of the material being dried.

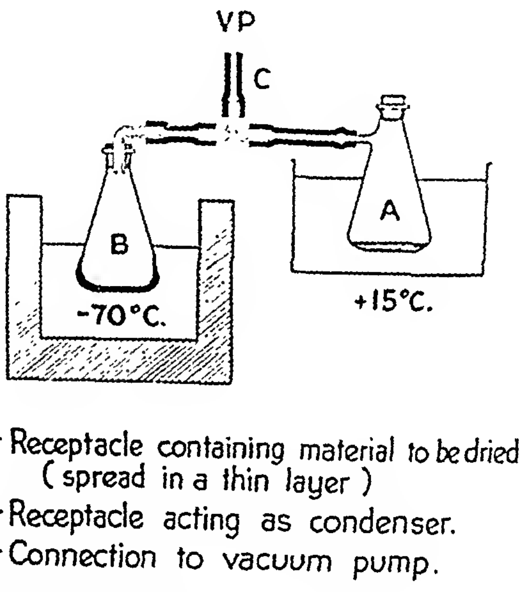

Fig. 1.—Bordas and d'Arsonval Apparatus for the drying of easily alterable substances.

Greaves and Adair[9] likewise found that the lowering of the condenser temperatures lowers the temperatures of the frozen material being dried to a very slight extent only. They successfully employed as refrigerating agent methyl chloride, and obtained temperatures of minus 52° C. to minus 42° C.

Greaves and Adair state that with temperatures of minus 45° C., the percentage of water remaining at the end of desiccation is much less than when higher temperatures are employed. We have found that with the water jacket of the drying chamber at plus 35° C. to plus 36° C. and temperatures of condensation of minus 30° C. to minus 35° C., the residual moisture of the resulting material is constantly less than 1 per cent.

The method employed for the determination of the residual moisture is that described by the National Institute of Health, i.e., drying of the material in high vacuum over phosphorus pentoxide to constant weight.

The great advantages in the employment of relatively high temperatures of water vapor condensation are, essentially, simplicity of operation and economy, since the heat neutralizing capacity of a compressor falls rapidly with the lowering of the temperature of condensation.

There are two methods of drying under vacuum which do not employ a condenser. One of these, the "desivac" machine,[10] allows the water vapor to enter the vacuum pump and constantly removes the water from the oil by means of a high speed centrifuge. The high cost of this apparatus and the relatively long drying time make its operation uneconomical. Another method produces a vacuum by means of multiple steam jets, in which case the water vapor escapes with the steam, thus eliminating the need for a condenser. This method is particularly suited to large quantity production on a commercial scale.[11]

With the possible exception of the method of Greaves and Adair, all of the above-mentioned methods require large and expensive apparatus to dry enough plasma to consider the process practical. In addition, the use of chemical desiccants requires redrying of the desiccant each time it is used, an operating entailing per se considerable time and expense.

An apparatus for the drying of plasma from the frozen state by low temperature water vapor condensation in vacuo, previously described by us,[12] was based on the principles laid down by Bordas and d'Arsonval and on the work of Shackell,[3d] Harris,[3c] and Rogers.[3e] In the construction of the drying chamber, advantage was taken for proper heat distribution to the material being dried of copper split cylinders or shells enveloping each bottle. These shells, properly fastened together, formed also a desirable method of handling the bottles during the loading of the drying chamber, making the operation easy and rapid. In the construction of the condenser, we took advantage of details of construction pointed out by Reichel[5] and by Flosdorf and Mudd.[6] This condenser was externally cooled by the use of alcohol-carbon dioxide ice mixture.

Routine use of this apparatus pointed out that while the drying chamber proved fairly satisfactory, the condenser was rather crude in design and expensive in operation, particularly because of the cost of carbon dioxide ice and the necessity for almost continuous supervision. The presence of a secondary condenser made the apparatus difficult to handle and proper insulation an almost impossible task with the result that much of the low temperature produced by the carbon dioxide ice was wasted. The time of drying was three days or more.

An attempt was made to eliminate the use of dry ice by cooling the condenser by the use of a low temperature, two-stage (cascade) compressor using Freon-12 (or propane) and ethane as refrigerants and of a circulating brine system giving a condensing temperature of about minus 60° C. This apparatus proved too bulky, expensive, and unreliable in performance.*

Our early choice of low temperatures, in the neighborhood of minus 60° C. to minus 70° C. for the operation of this condenser as well as for the prefreezing of the plasma, was suggested by the generally held idea that such low temperatures were essential for the proper preservation of the product as well as for the proper functioning of the apparatus.[5, 6]

*Better two-stage compressors are built today, but they do not offer any practical advantage by the use of lower temperatures to offset the greater cost of purchase and maintenance.

DESCRIPTION OF NEW APPARATUS

The construction of a condenser with refrigerated coils within the condenser chamber was next attempted. Coils within the condenser are more efficient because of the excellent insulation provided by the high vacuum. This condenser was and is being used with a drying chamber similar to the one previously described.

The standard apparatus described here is capable of drying, in less than twenty-four hours, twenty-four lots of plasma each containing 300 c.c. in a 400 c.c. container. Thus the capacity is 7,200 c.c. in twenty-four hours. The residual moisture of plasma dried in this apparatus is consistently well below 1 per cent of the weight of the remaining material, assuring adequate preservation and rapid solution when the plasma is restored with solvent.*

It is to be noted that the time of drying depends upon several factors. The most important are as follows:

1. The thickness of the shell of the frozen material. A thinner shell dries much more rapidly than a thick one.

2. The amount of heat applied to the frozen material in the process of drying. The more heat applied, the more rapid is the process. Details of the application of heat will be elaborated upon separately.

3. The diameter of the neck of the bottle. The larger the opening, the more rapid the process within certain limits.

4. The type of protection used to maintain sterility. In our method sterility is adequately maintained by covering the individual bottles with a large cuff made from two layers of 40-mesh gauze. This offers some resistance to the flow of water vapor and, therefore, lengthens the time required for drying. It is felt, however, that this is a desirable precaution against contamination.

The complete apparatus described here is used for prefreezing (shell freezing) the plasma and for drying the plasma from the frozen state. It consists of four main parts: (1) a mechanical shelling apparatus, (2) a drying chamber with a water jacket, (3) a condenser with a mechanically refrigerated coil, and (4) a vacuum pump.

1. *Shelling Apparatus* (Fig. 2).—This consists of an insulated metal pan, containing the cooling coils and the apparatus for rotating the bottles containing the plasma.

The cooling coil is formed of a series of straight copper tubes. The two center tubes are shorter to make room for a propeller which circulates the cold alcohol. A plate type evaporator of suitable capacity may be used instead of coils. The shelling pan is connected with a reservoir for the alcohol. Before use, alcohol is pumped into the shelling pan. At the end of the process, the alcohol is returned to the reservoir by gravity. The shelling pan contains a mechanical device, capable of turning twelve bottles at the rate of one-half to one rotation per minute. The arrangement of the rotating wheels is so that the bottles will be immersed in the cooled alcohol about 12 mm.

*The standard apparatus here described is constructed by the Precision Scientific Company of Chicago.

2. *Drying Chamber* (Fig. 3).—The drying chamber consists of a heavy brass cylinder (22.5 cm. in diameter and 70 cm. high) surrounded by a water jacket. It is closed on top by a heavy steel lid, which rests on a rubber gasket. The lid may be tightened by threaded lugs and wing nuts. The opening for the connection with the condenser is in the middle of the base of the drying chamber. This location constitutes an essential feature of the apparatus. It is flush with the base itself and is 5 cm. (2 inches) in diameter. The connection with the condenser is made by a short copper pipe, 5 cm. (2 inches) in diameter.

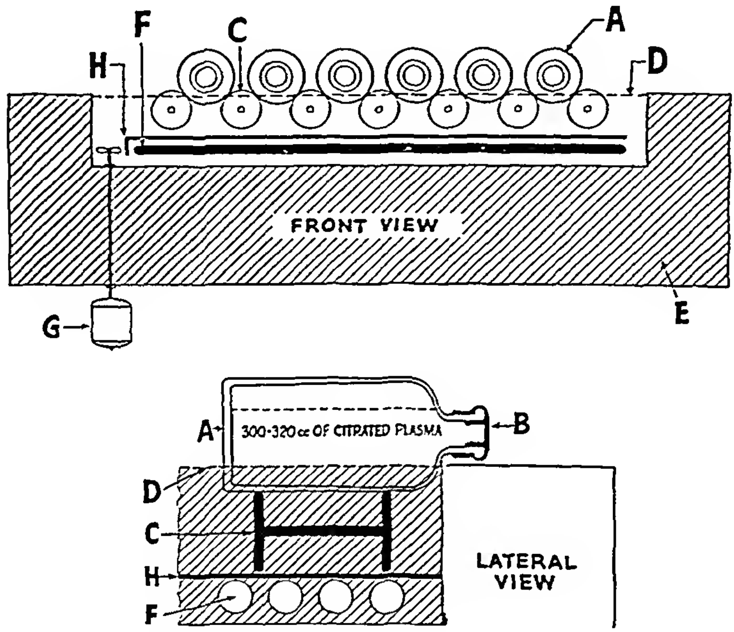

Fig. 2.—Apparatus for shell freezing with circulator for refrigerated alcohol (schematic). *A*, 400 c.c. bottle; *B*, rubber stopper; *C*, rubber-tired rollers; *D*, refrigerated alcohol level; *E*, insulated metal pan; *F*, evaporator coils; *G*, circulator; *H*, baffle board.

The drying chamber is surrounded by a water jacket formed by a cylinder of rustproof metal fixed to the flange of the inner chamber. The water jacket is 30 cm. (12 inches) in diameter and 90 cm. (36 inches) overall in length. It is provided with an electrical heater, fitted to the bottom and capable of maintaining the water at any desired temperature up to 80° C. This heater is controlled by a thermostat and relay. The temperature may be adjusted by setting the thermostat. The water bath is connected by pipes to sources of hot and cold water.

The dry chamber is fitted with four copper baskets. Each basket is composed of an outer split cylinder of 24 oz. copper approximately 22.5 cm. in diameter (9 inches) and 20 cm. in height (7⅞ inches). The lower border is turned in 12 mm. (½ inch). This strengthens the cylinder and holds the plasma bottles in place. This large cylinder contains a series of six smaller split copper cylinders welded to the inner surface. These are 11.8 cm. high (4⅝ inches) and are of the proper diameter to grip the plasma bottle tightly. The basket is completed by a transverse bar and springs, which maintain proper expansion

of the outer cylinder, and by a series of copper wedges, which assist in increasing heat condution as well as the contact of the copper shells with the bottles.

A recording thermometer is provided to determine the temperature of one of the copper shells of the lower basket. It has a range from minus 10° C. to plus 80° C. The bulb of the thermometer is fixed to the bottom of the drying chamber and is in direct contact with two of the copper cylinders. Its reading is affected by the temperature of the bottle of plasma in the copper cylinders. A dial thermometer shows the temperature of the water bath. When the temperature shown by these two thermometers remains within 42° C. for two hours or more, the plasma may be considered dry.

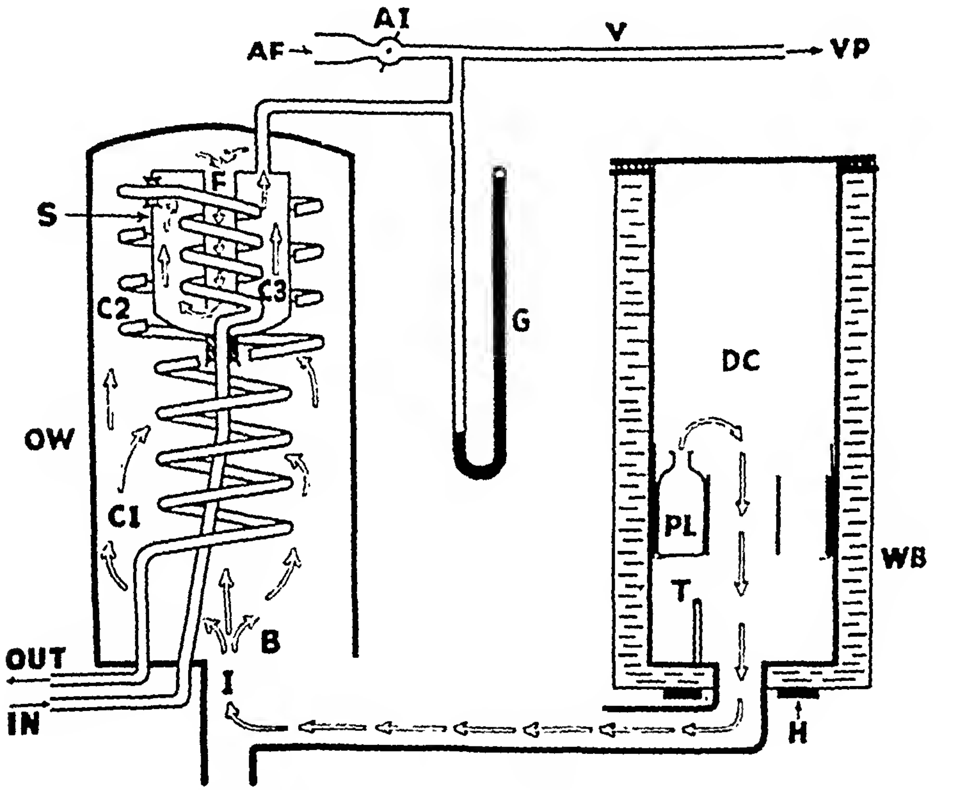

Fig. 3.—Apparatus for drying of plasma (semischematic).

IN, Inlet of evaporator; *OUT*, o[illegible] *OW*, wall of condenser chamber; *C1-C2-C3*, portions of the evaporator ([illegible] *I*, inlet for water vapor; *F*, funnel-like opening conveying water vapors f[illegible] denser chamber to the coldest portion of the evaporator coil, *C3*; *B*, base of the condenser chamber; *G*, vacuum gauge; *AF*, air filter; *AI*, air inlet valve; *V*, vacuum line; *VP*, vacuum pump; *H*, 750 Watt heater; *WB*, water bath; *DC*, drying chamber; *Pl*, plasma; *S*, shield of condenser; *T*, bulb of recording thermometer.

One of the difficulties in the drying of plasma from the frozen state is the proper application of heat to the frozen plasma to counteract the cooling effect of rapid evaporation. If no heat is applied, the process will require several days, while properly controlled heating reduces the time to less than twenty-four hours. Heat from the water bath around the drying chamber is conducted to the plasma very satisfactorily by means of the copper baskets just described.

3. *Condenser* (Fig. 3).—In the construction of the condenser there are two essential features:

1. The large water vapor inlet is located in the lowest part of the condensing chamber.

2. The refrigerated coils are so arranged that by means of properly placed cylindrical shields, the water vapor is made to travel a long distance and come in contact with a large condensing surface. The last portion of the coil with which the vapor comes in contact is the coldest. This assures condensation of all of the water vapor and prevents any water from mixing with the oil of the vacuum pump.

The water vapor enters the condenser from the bottom. This is very important, because it allows slower diffusion of the water vapor and allows maximal condensation on the first set of coils with which the vapor comes in contact. Under ordinary conditions, the greatest portion of the vapor is condensed on Coil C1. Some vapor escapes Coil C1 and reaches Coil C2. Here the vapor travels through a rather narrow space between the wall of the condenser and the cylindrical copper shield S placed inside of Coil C2. If a trace of water vapor escapes Coil C2, it must travel through a narrow funnellike tube (F) to reach Coil C3 which is enclosed in a copper box. The vacuum pump is connected to the condenser by means of an opening in the top of this box. The great bulk of the water vapor is condensed on Coil C1, a smaller amount on Coil C2, and only a trace on Coil C3 (Fig. 4). No water escapes to the vacuum pump. This has been determined by placing a copper U-tube 5 cm. in diameter in the vacuum line V during experimental runs. The U-tube was immersed in a bath of carbon dioxide ice and alcohol maintaining a temperature of minus 70° C. to minus 72° C. At the end of the runs no ice was found in the U-tube.

A Servel F-12, four-cylinder, ¾ h.p. compressor with dehydrator and oil separator is very satisfactory for cooling the coils in the shelling pan and in the condenser. The shelling pan and the condenser may be cooled simultaneously or individually. The F-12 gas should be pumped out of the coils before heat is applied in the condenser to melt the ice at the end of each run. The coils in the condenser will be maintained from minus 35° C. to minus 40° C. without a load, and from minus 30° C. to minus 35° C. while the drying is being accomplished. Occasionally during the period of maximal condensation, the temperature may be a little higher.

The condenser chamber itself is made of copper sufficiently strong to withstand a high vacuum. The total length of the refrigerated coil is 13 m. (44 feet), and the inner diameter 1.56 mm. (⅝ inch). A dial thermometer shows the temperature of the "In" coil of the condenser. This greatly assists in checking proper operation of the refrigerating compressor. An electric heater is provided in the condenser to melt the ice from the coils rapidly at the end of each drying run. The melted ice is then drained from the condenser through the opening in the bottom.

The copper box (S of Fig. 3) is so constructed that the ice formed on Coil C3 will drain out once it is melted. This is accomplished by means of a self-sealing valve surrounding the "In" coil as it enters the box. The valve consists of a short length of copper tube insulated from the rest of the box and approx-

imately 2 mm. larger in diameter than the refrigerated coil passing through it. When the drying process is initiated, water vapor very soon freezes around the refrigerated coil passing through the valve, and so seals it. When the ice is melted, the valve is open and allows water from Coil C3 to drain from the condenser.

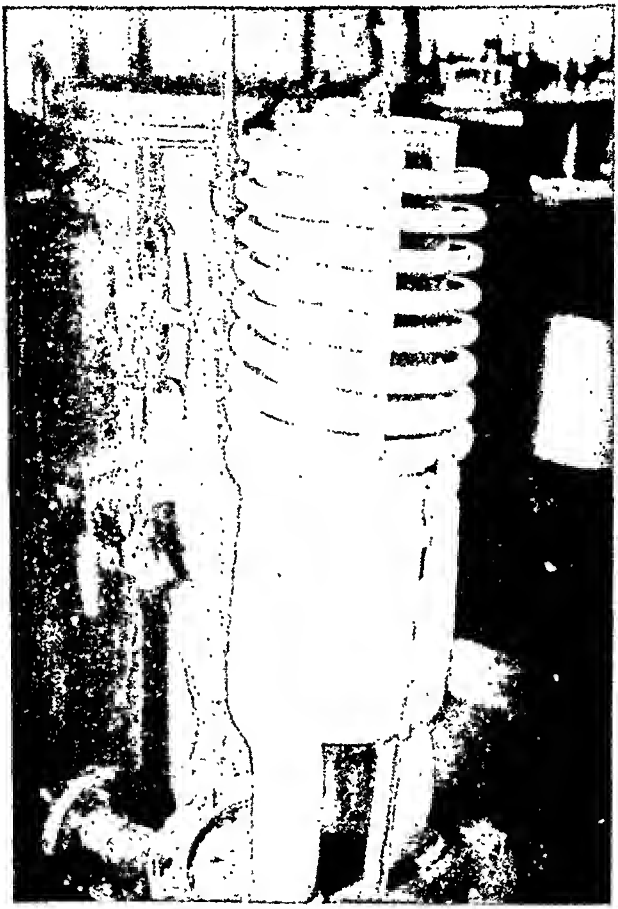

Fig. 4.—Ice formation on the condensing coil after a standard run (about 7200 c.c.)

4. *Vacuum Pump and Gauge.*—The large Welch Duo-Seal or the Cenco-Megavac with ½ h.p. motor has proved adequate. The pump must have a capacity sufficient to evacuate the system to a pressure of less than 2500 microns in ten minutes and 500 microns in less than fifteen minutes with the temperature of the condensing coils at minus 30° C. to minus 40° C.

A Pirani type vacuum gauge, such as the Truvac Gauge, Model 12, is satisfactory. It should be graduated from 2500 microns to 0 microns. A MacLeod type mercury gauge is also satisfactory. It is desirable to have, in addition, a rough dial type vacuum gauge, reading from atmospheric pressure to zero, to be able at a glance to watch the initial rate of evacuation of the system when a drying run is being started. This ascertains, in the first minute or so, that all outlets have been properly closed.

The entire apparatus is compactly assembled in a single cabinet and all switches, valves and recording dials and instruments are placed on a single panel (Fig. 5).

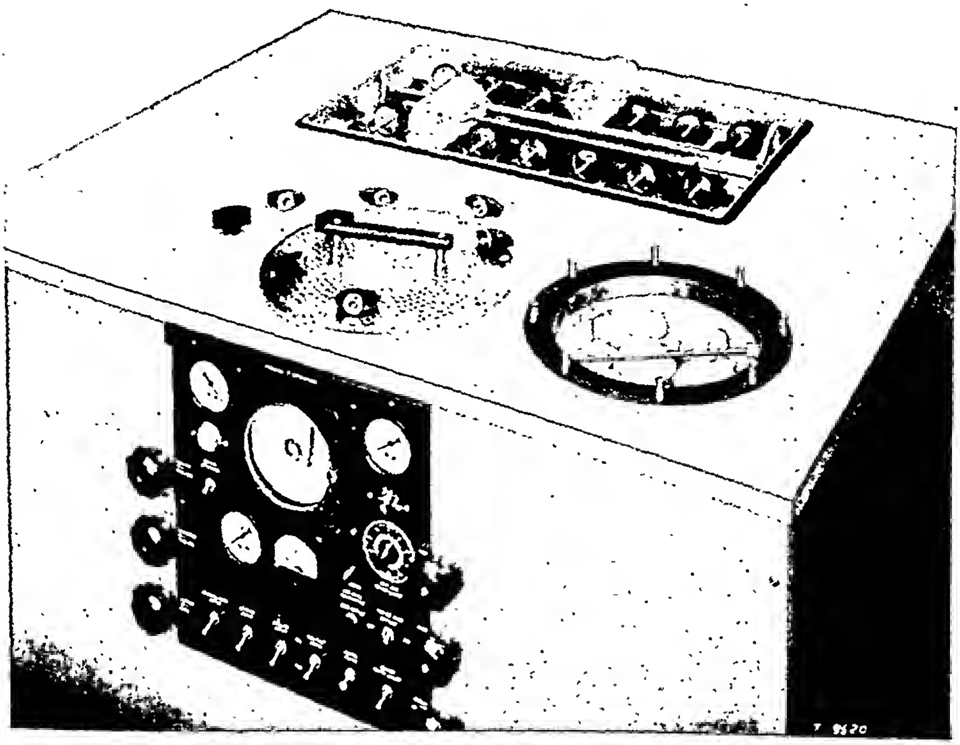

Fig. 5.—Standard shell freezing and drying apparatus. In the rear can be seen the shelling pan; in the right anterior corner the drying chamber, and in the middle front the panel board.

MECHANICAL SHELL FREEZING AT MINUS 20° C. TO MINUS 35° C.

We had previously found that the choice of low temperatures in the neighborhood of minus 60° C. to minus 70° C. for rapid prefreezing of plasma does not offer any practical advantage. A mechanical apparatus which gave good results[1a] was developed for shell freezing at minus 40° C. It was found, however, that shell freezing at temperatures higher than minus 40° C. was not possible with continuous rotation, because plasma would become supercooled at minus 6° C. to minus 12° C., and would then "snap" freeze, with slushing and formation of an irregular shell, with large lumps which greatly interfered with drying later on.

In attempting to shell freeze plasma at temperatures between minus 20° C. and minus 35° C., it was noted that if early initial local freezing occurred in contact with the inner surface of the bottle, shell freezing continued thereafter without lumping. It appeared necessary in the course of experimental work to produce a relatively rapid cooling of plasma to about plus 10° C. from room temperature followed by local freezing, to avoid supercooling of the entire mass and slushing following "snap" freezing. This is accomplished with the fol-

lowing technique: The plasma bottle is rotated slowly (½ to 1 r.p.m.) with 12 mm. immersion in alcohol cooled to minus 30° C. to minus 35° C. for a period sufficiently long to bring the temperature down to about plus 10° C. The length of time required for this operation depends chiefly on: (a) the temperature of plasma, and (b) the temperature of the brine. It varies from three to ten minutes. With plasma at plus 25° C. and the brine at minus 30° C., about ten minutes are sufficient. After the period of cooling, the rotation is stopped long enough to cause the lower portion of the plasma to "snap" freeze to a depth of about 3 to 4 mm. This requires two to four minutes. The phenomenon is, as a rule, clearly visible. It is important to remember that during this period of time, the bottle of plasma must not be disturbed, and that the depth of immersion of the bottle in the cooled alcohol must be 10 to 12 mm. only. Occasionally, and for no apparent reason, one bottle may take considerably longer to show initial "snap" freezing. It must not be disturbed until "snap" freezing has occurred. It is desirable to obtain a temperature of minus 35° C. or a little lower before placing the bottles in the shelling pan.

When the local "snap" freezing has occurred in all of the bottles, the rotating motion is resumed, and shell freezing occurs at a regular rate and very evenly. With a temperature varying between minus 35° C. and minus 25° C., it requires one hour and fifteen minutes to one hour and twenty-five minutes for complete shell freezing of 300 c.c. of plasma. The quality of the material thus frozen is practically identical with that obtained from shell freezing at minus 70° C. The material thus obtained is readily recognized as it shows a longitudinal portion of microcrystalline, homogeneous aspect, lighter in color, and about 4 to 5 cm. wide and 3 to 4 mm. thick. The remaining portion shows a macrocrystalline structure. This aspect is clearly retained after drying from the frozen state (Fig. 6).

When the plasma is shelled, the bottles are placed in a storage cabinet at minus 20° C. to minus 30° C. to cool. It takes about four hours for the frozen material to cool from about 0° C. to minus 20° C. The plasma thus shelled can remain in cold storage for an indefinite period of time.[15]

About one hour before initiating the drying process, the copper baskets are placed in the low temperature cabinet to cool. At the same time, the bottles of shell-frozen plasma are removed, one by one, from the storage cabinet and, under aseptic precautions, the rubber stoppers are replaced by large sterile gauze cuffs formed of two layers of 40-mesh gauze. The bottles are now placed in the copper baskets, and allowed to cool for about one-half hour at minus 20° C. to minus 30° C.

TESTING AND OPERATION OF THE APPARATUS

Before each run the apparatus should be tested to be sure it will produce a satisfactory vacuum and low temperature. The drying chamber and the inlet valve are closed, and the compressor is started and allowed to run until the thermometer on the condensing coil registers minus 30° C. or less. The vacuum pump may then be started and a vacuum of 500 microns (Truvac gauge) or less must be obtained in fifteen minutes or less. If this is accomplished, the vacuum pump is shut down, the vacuum is released, and the drying chamber opened.

The copper baskets containing the shell-frozen plasma are rapidly placed in the chamber, the lid is closed, and the vacuum pump started. This operation can readily be accomplished in about two minutes. A pressure of 500 microns or less should be attained in fifteen minutes or less to avoid danger of thawing. The water in the water jacket of the drying chamber must be cool, not over 25° C.

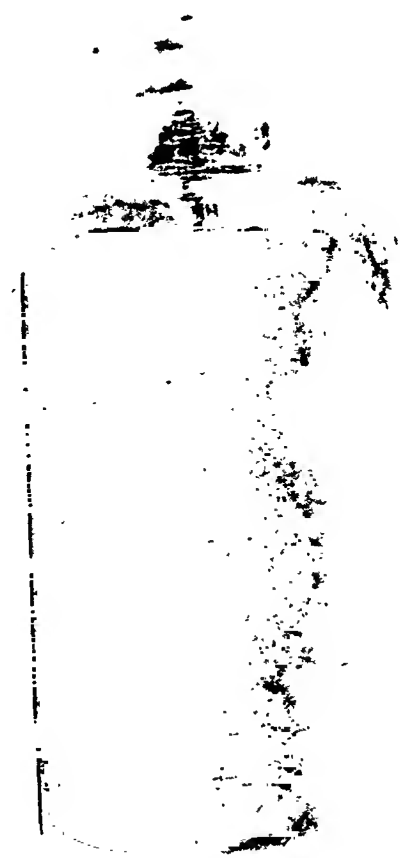

Fig. 6.—Bottle of dried plasma showing on the left homogeneous aspect corresponding to the portion of plasma "snap" frozen, and on the right the gross crystalline structure prevailing in the remaining portion.

The operation is allowed to proceed for one hour. The heater of the water jacket is then turned on with the thermostat set at plus 50° C. Drying is allowed to proceed until the thermometer recording the temperature of the plasma has been for two hours or more within two degrees of the temperature of the water in the water jacket. The vacuum pump is then stopped, and filtered air is allowed to enter slowly through the inlet valve. This air passes through the condenser before it enters the drying chamber and thus is dried. The opening of the inlet valve is covered with 40 to 50 layers of gauze to effect a good filtration of air, sufficient per se to minimize danger of contamination. The air should be allowed to enter slowly, taking about five minutes for the entire operation. The copper baskets are removed one at a time, and the bottles promptly stoppered.[12] The bottles are then evacuated, and the rubber stoppers are covered

with gel caps. This method of closure is sufficient for preservation up to three years. If the preservation is to be for longer periods of time, the material is vacuum-sealed in tin cans.[14]

The time of drying with a continuous temperature of 50° C. in the water jacket is less than eighteen hours. When it is desirable to reduce the drying time, the temperature of the water jacket may be increased up to 80° C. for a period of time.

The dried plasma obtained with the apparatus and technique outlined above is a light, porous material, with a distinct crystalline structure, and a volume slightly less than that occupied by the frozen plasma. It may be readily reduced to a fluffy powder by shaking, in which case it occupies about one-third of the original volume. The powder thus obtained is readily transferred to another receptacle for purpose of residual moisture determination or of combining the content of two or more bottles. The color of the dried plasma is light amber, when the original liquid plasma had a hemoglobin content of less than 5 mg. It is very soluble in water. When solvent is introduced by vacuum suction, dried plasma containing 17.5 Gm. of plasma proteins (the equivalent of about 300 c.c. of fresh citrated plasma) dissolves entirely in 250 c.c. of distilled water or 0.1 per cent citric acid solution in less than one minute, including the time consumed by the introduction of the solvent.

The resulting fluid is stable at room temperature for at least several days; it has a maximal content of complement, and a maximal content of prothrombin if regenerated with 0.1 per cent citric acid solution.[17] The use intravenously of properly prepared material causes no untoward reactions, save an occasional (less than 1 per cent) urticarial reaction.

The size of the apparatus here described is considered best for the purpose intended, namely, for large hospitals to dry plasma for their own use and for neighboring institutions. Both smaller (1800 c.c. daily capacity) and larger (21,600 c.c. daily capacity) units have been successfully operated, however. When larger units for commercial operation are built, it is desirable to institute automatic temperature control, for minimum drying time with the least technical supervision, by the installation of a cam-type combination thermoregulator and recording apparatus, such as the one furnished by the Foxboro Company, Mass.

In addition to human plasma, serum, guinea pig complement, bacterial cultures, milk, many fruit juices, culture media, and even meats and other products have been dried with the machine here described with excellent preservation of all essential properties including flavor and vitamin content.

The advantages of the apparatus here described over other apparatus are:

1. Both prefreezing in shell form and drying from the frozen state are accomplished by employing the same economical source of low temperature.

2. The apparatus is very simple in operation and almost entirely automatic.

3. It yields constantly a product in every way satisfying the requirements set forth by the National Institute of Health.

4. The time of drying is considerably shorter than that obtained with other methods.

5. The total cost of operation per unit is very small.

A NEW FIBRINOLYTIC METHOD FOR THE ASSAY OF PROTEASES AND ITS APPLICATION TO AN ANALYSIS OF COAGULATION PHENOMENA IN RABBIT BLOOD*

JOHN H. FERGUSON, M.D., ANN ARBOR, MICH.

SINCE 1939, this laboratory has been contributing evidence for a new theory[1] of blood-clotting, based upon the dominant role of serum-tryptase, a proteolytic enzyme, long recognized by biochemists (Oppenheimer[2]). Even in the complete absence of formed elements, this plasma enzyme normally performs actions which we are able to duplicate with *crystalline* (pancreatic) trypsin, in vitro. These actions are (1) thromboplastic conversion of prothrombin to thrombin[1b, 3] (whence the designation "thromboplastic enzyme"[4]), (2) digestion of prothrombin[5] and thrombin[6] (whence the term "progressive" antithrombin to distinguish the latter from "immediate," neutralizing and reversible[7] inhibition of thrombin, for example by heparin and its albumin-fraction "cofactor"), (3) lysis of fibrinogen and fibrin[8] (whence the term "fibrinolysin" is superfluous). Clot retraction is probably just the initial phase of tryptic digestion of the clot, and natural fibrinolysis plays an important role in the resolution of (blood) clots in vivo.[8] Ferguson's claim that a plasma deficiency of available tryptase is the true explanation of the coagulation delay in *hemophilia*,[9] has been confirmed by Feissly,[10] with the aid of a gelatine liquefaction technique. Continued search for a method whereby this and other problems relating to the tryptase factor could be put to a quantitative test, has yielded a new assay technique, as follows:

ASSAY OF TRYPSIN BY FIBRINOLYSIS

(*Relative Turbidimetry With the Photoelectric Colorimeter*). *Method.*[11]—Varying amounts of trypsin are added to alkaline (buffered) mixtures of fibrinogen and thrombin and lysis of the clots formed is timed by the relative positions of the curves charted with the aid of the Evelyn apparatus.

Reagents.—The test requires a stable fibrinogen and a stable thrombin. Citrated blood plasma contains a natural lytic factor (serum tryptase), but this apparently deteriorates on keeping. Hence, the *fibrinogen* (F) is routinely prepared by three precipitations with $(NH_4)_2SO_4$ (¼ sat.), from refiltered (dog) plasma, several days old. The preparation is suitable if it shows no visible lysis (in the control) during the course of the experiment. An excellent stable *thrombin* (T_0) is obtained by a 1:100 dilution of Parfentjev's[12] "rabbit clotting globulin" (Lederle Laboratories). In an optimal series of *trypsin* dilutions, the highest enzyme concentration used causes fibrinolysis in one and one-half to two hours and the weakest in six to twelve hours (a matter of convenience). The strongest typsin should not significantly interfere with clot formation. All reagents contain 0.9 per cent NaCl (plus thymol) and

*From the Department of Pharmacology, Medical School, University of Michigan.
Received for publication, Sept. 21, 1942.

the fibrinogen is buffered with barbiturate,[6] borate, or other suitable buffer. A routine pH of 7.5-7.75 is sufficiently alkaline for the enzyme action, without increasing the translucency (impairing turbidity) to the extent seen with unduly alkaline mixtures. The following amounts of reagents are mixed in the order cited: 5 c.c. *buffered* fibrinogen + 1 c.c. saline (= control for experiments on inhibitor or other agents it is desired to study) + 3 c.c. thrombin + 1 c.c. trypsin. In order to minimize lysis of the fibrinogen and thrombin, the enzyme is added five to ten seconds before the onset of clotting.

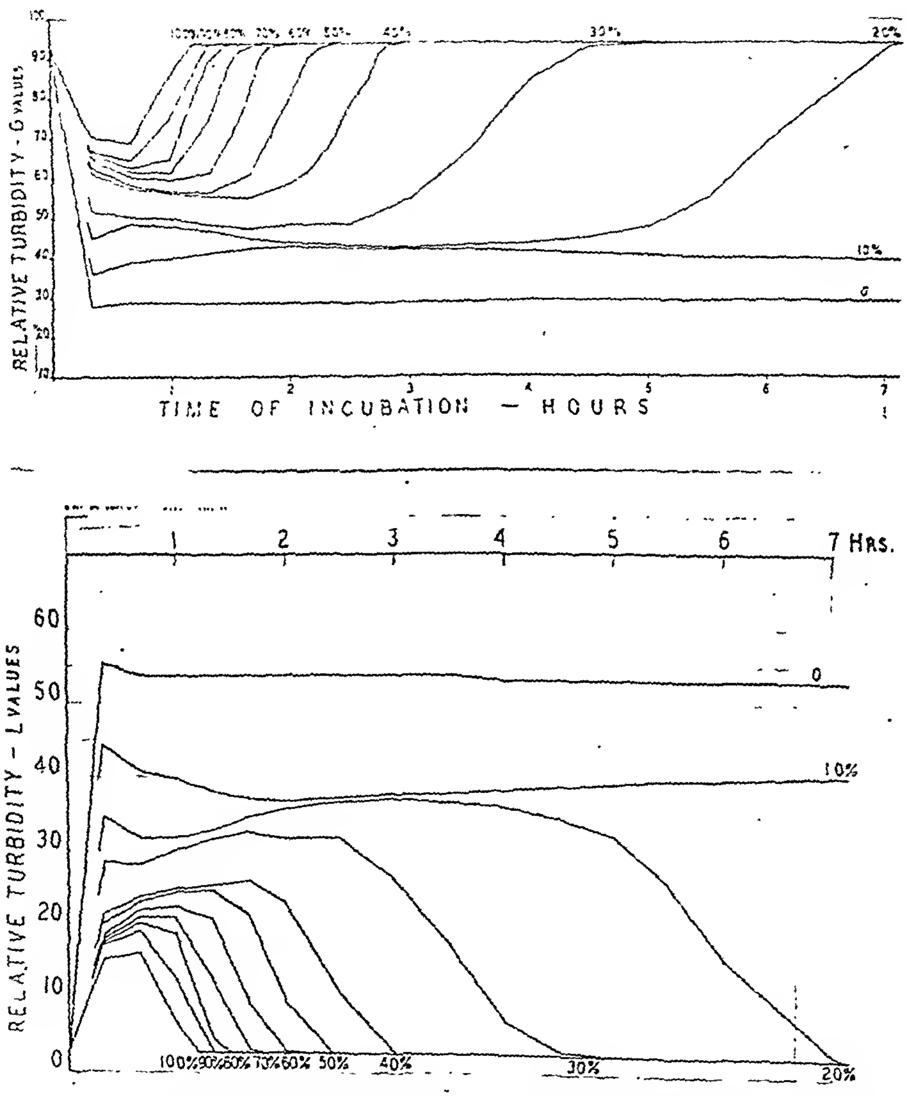

Fig. 1.—Assay of crystalline trypsin (standard X.T.) by fibrinolysis. Relative turbidimetry with the Evelyn photoelectric colorimeter. 1·10 vol. of 1:1000 X.T. = 100%. Temp. = 22° C., $pH = 7.5$.

Data.—The data presented graphically in Fig. 1 form a typical reference series on a crystalline trypsin preparation, 1 mg. of which analyzed 4.24×10^{-3} [T.U.]m, by the Anson and Mirsky method.[13] Ten per cent fractions of a stock (100 per cent = 1:4000) were used in one-tenth vol. (v. supra), hence the *final* concentrations vary from 1:40,000 down to 1:400,000. The curve for 1:400,000

(10 per cent) is incomplete since fibrinolysis in this case required 15 to 16 hours, as compared with 7 hours, 5 hours, 3 hours, 145 minutes, 130 minutes, 110 minutes, 90 minutes, 80 minutes, 72 minutes, for the 20 per cent to 100 per cent, respectively. The control was completely unaffected in 24 to 48 hours. Temp. = 22° C., pH = 7.5 (checked in all tubes, with glass electrode, at completion of fibrinolysis). Clotting-time (C.T.) = 25 seconds: the same in the control and all the enzyme-containing mixtures.

Instrument data.—Green filter (510). Galvanometer (G) values: (1) Blank (10 c.c. saline) = 1000; (2) initial reading (all tubes) = 930; (3) final reading (all tubes, except control) = 910.

The slight persistent turbidity is due to a very faint opalescence, probably associated with traces of lipids or thrombin impurities which are still present after fibrinolysis.

Comment.—The absence of C.T. change is evidence that the thrombin and fibrinogen are not significantly attacked by the trypsin concentrations used. However, the relative turbidity is progressively lessened as the enzyme strength is increased (see Fig. 1) and this is probably a more sensitive indication of a minor degree of fibrinogen destruction. Such fibrinogenolysis as may occur enhances the sensitivity of the turbidimetric test, but lessens the significance of the actual values. It is not the shape of the curves which is significant, but their relative positions along the time axis. A simple charting of galvanometer scale readings (G) serves the purpose of *timing* the fibrinolysis just as satisfactorily as the corresponding "photometric densities" (L), which require computation by the formula L = 2 – log G. Both methods are illustrated in Fig. 1. The steep terminations of the curves for the various mixtures are clearly separated by marked time differences. Hence, the strength of any "unknown" solution of similarly-acting lytic agent (suitably diluted) can be assayed from the position of its end-curve with reference to those for the standard trypsins. A good commercial trypsin of known potency is just as serviceable as the crystalline enzyme.* The 10 per cent "limit of error" is extremely liberal, particularly with the longer-acting (i. e. weaker) trypsins.

In preliminary testing for suitable dilution range, simple visual timing of fibrinolysis is adequate and the photometer can also be dispensed with if the "lytic times" are sufficiently long and well separated. Turbidimetry is invaluable, however, for enhancing the reliability of observation and permitting assays to be made with the greatest possible accuracy in the shorter time intervals. The absolute practical sensitivity of the fibrinolytic assay is of the order of 1:1,000,000 final crystalline trypsin ($=4.24 \times 10^{-6}$ $[\mathrm{T.U.}]_{\mathrm{Hb}}$), which makes the method especially applicable to quantities of enzyme too small to be assayed by all but the best (Anson and Mirsky[13]) proteolytic methods. It offers three improvements over the method used for bacterial "fibrinolysin" by Christensen:[14] (1) standard reference enzyme, (2) greater accuracy of the photoelectric timing, (3) an absolutely stable (tryptase-free) fibrinogen is not essential. A trace (0.1 per cent) of citrate is not objectionable, but tryptase inhibitors must be absent.

*Further detail as to standard "units" and reagents is given in a note to Federation Proc. (1943). A Newer Method, by Lysis of Fibrinogen, Proc. Soc. Exper. Biol. & Med. 52: 243, 1943.

Effects of Varying Fibrinogen Concentration. Method.—Five strengths of a fibrinogen solution (v. supra), which yielded 200 mg. of *fibrin* per 100 c.c. (dry weight, by a modified Gram method), were clotted by T_6 (as above) in the presence of 1/10 volume of 1:4000, 1:8000, 1:16000, 1:32000 N.T., along with a control (without trypsin) for each series. Table I summarizes both the clotting-times and the "lytic times," determined with the aid of the photoelectric colorimeter.

Comment.—As expected, the rate of fibrinolysis is speeded up by lowering the substrate (fibrin) concentration. The clotting-times indicate that the 0.2 per cent fibrinogen was a little too strong for optimal clotting and gave slowest lysis with both strongest and weakest enzyme concentration. The 0.0125 per cent fibrinogen was too weak, giving longer clotting-time (hence favoring fibrinogenolysis by the added enzyme) and insufficient turbidity. Nevertheless, the control remained stable for three days and the turbidimetric timing of the lysis seemed satisfactory. It was particularly noted that the weaker fibrins gave quicker lysis with both the strongest and weakest enzyme concentrations. The facts suggest a trace of *natural inhibitor* in the fibrinogen. With intermediate enzyme concentration (final conc. = 1:80,000, 1:160,000) the varying fibrinogen produced only minor differences in the lytic times. It may be concluded that a fibrinogen concentration of 0.05 to 0.1 per cent is optimal for the trypsin assay. With trypsin concentrations below 1:300,000 (final), somewhat weaker fibrinogens may be advocated.

Effects of Temperature and pH.—Our experience confirms the information given by Christensen, for bacterial "fibrinolysins," and the data need not be presented in detail. We find it convenient to carry out the lytic tests at room temperature (20° to 25° C.) and a thermostat water-bath is indicated only for timing lysis occurring more rapidly than two hours. Tryspin has a broad zone of optimal pH (8 to 9. Northrop) and considerable activity is retained well into the acid side of neutrality. The fibrinolytic method is adapted to the assay of any proteolytic enzymes which are active between pH = 6.5 and 8.5. Too great alkalinity lessens the "photometric density" of the fibrin gel, leading us to prefer a pH = 7.5 – 7.75 as the practical optimum for the method, albeit this is about the limit of usefulness of the barbiturate buffer recommended (since barbituric acid tends to precipitate from the buffer mixture).

TABLE I

EFFECTS OF VARYING FIBRINOGEN CONCENTRATION ON ASSAY OF TRYPSIN BY FIBRINOLYSIS. "LYTIC TIMES" AT 25° C., pH = 7.5

FIBRINOGEN CONC. (%)	0.2	0.1	0.05	0.025	0.0125
Trypsin conc. (final)					
1:40,000	75 min.	60 min.	45 min.	40 min.	35 min.
1:80,000	2 hr.	2½ hr.	1¾ hr.	1½ hr.	1¼ hr.
1:160,000	3½ hr.	4 hr.	3 hr.	3 hr.	2¼ hr.
1:320,000	9 hr.	7½ hr.	5 hr.	5 hr.	3½ hr.
0*	∞	∞	∞	∞	∞
Clotting-times	30 sec.	25 sec.	25 sec.	26 sec.	55 sec.

*None of the controls showed any lysis in 3 days. The clotting-times are for the controls, but were not significantly modified by the addition of enzyme in the manner specified.

Use With Other Proteases.—The new method obviously suggests application to the study of all "tryptases" (Oppenheimer[2]) including *those* of plasma, leucocyte (and platelet), and tissue origin; also bacterial proteases and the

proteases in snake venoms (which may possibly have a bacterial origin), and papain. It is an easy way to control steps in the purification of such enzymes and their behavior with respect to small changes in pH, salt concentration, action of inhibitors, etc.

SERUM-TRYPTASE AND BLOOD-CLOTTING IN THE RABBIT

The following materials were tested: A, 10 c.c. citrated (0.38 per cent) rabbit plasma, diluted to routine volume (25 c.c.) with thymol-saline; B, same (1:2 dilution) citrated plasma clotted by *excess* of $CaCl_2$, the fibrin being removed by whipping with a glass rod, leaving the clear serum for the chloroform treatment (infra); C, (1:2) citrated plasma, clotted by 2 *c.c.* enzyme-free thrombin (1:100 dilution of Parfentjev's rabbit globulin), the fibrin likewise being removed; D, the fibrin from C, washed thoroughly in three changes of saline and resuspended in routine volume (25 c.c.) of saline; E, ten-hour-old serum from clotted whole blood. In order to remove trypsin-inhibitors (which will not be considered at this time), we employed the old method of Nolf, et al. (Tagnon[15]), shaking with one-tenth volume of chloroform. The (50 c.c.) bottles were centrifuged after three-quarters of an hour, the supernatant being left in contact with the $CHCl_3$ and samples removed 1, 6, 24 hours from start of treatment. Clotting-tests and controlled fibrinolytic studies (routine trypsin-assay method) are summarized in Table II.

TABLE II

CLOTTING AND FIBRINOLYTIC TESTS ON RABBIT PLASMA MATERIALS

		CHLOROFORM TREATMENT			CLOT RETN.	LYSIS OF CLOT	LYTIC TIME (TRYPTASE TEST)
		(A) 1 HR.	(B) 6 HR.	(C) 24 HR.			
A	Plasma (citrated)	0 (24 hr.)	27 min. (+)	36 min. (+)	*none*	*none*	>4 days
B	Serum (excess Ca)	135 sec. (++)	40 sec. (++)	20 sec. (++)	3½ hr.	3-4 da.	40 hr.
C	Serum (Thrombic)	1 hr. (+)	0 (24 hr.)	2 hr. (+)	2nd day	3-4 da.	29 hr.
D	Fibrin (from C.)	51 min. (+)	12 min. (+)	58 min. (+)	2nd day	3-4 da.	20 hr.
E	Ten-hour serum (whole bld.)*	24 min. (++)	–	–	none	none	>4 days
F	Control (F + T_0)	35 sec. (++)	–	–	40 hr.	48 hr.	48 hr.

*0.1 c.c. serum + 1.0 F. A similar test with fresh (10 hr.) untreated serum clotted in 28 min.

TRYPTASE TESTS

Room temperature = 23° C. ± 2° C. pH = 7.75 (barbiturate buffer). 1 c.c. test-material in 10 c.c. fibrinogen-citrate (0.03 per cent)-buffer mixture. Standard trypsins: X.T. (v. supra) — 1:500,000; 1:1,000,000; 1:2,000,000 (final concentration) gave "lytic times" of 12½, 18, 24 hours, respectively, while the control (F) was stable for two days. Tests were made both with

the one-hour and the 24-hour samples, the latter with a weaker (1:3) fibrinogen. Except for a very slight increase in enzyme activity in *B* in the 24-hour, as compared with the one-hour sample, the data (including standards) were so similar that only the tests with the one-hour materials will be cited (Table II).

Data.—*A* and *E* showed no digestive activity in four days. Indeed, they were more stable than the control (F.) of 48 hours "lytic time," suggesting the presence of an *anti*-tryptase factor. In *D*, fibrinolysis was complete in 20 hours, with *C* not far behind (29 hours). *B* (one-hour sample) was weakly postive, with digestion about half completed in 36 hours, and quite clear in 40 hours (when the control was just beginning to lyse). All tests indicate very little enzyme and fall below the satisfactory working range of the method. Even so, the data are valuable and, allowing for the plasma dilution (final = 1:25), it can be stated with some assurance, that the rabbit plasma (serum) materials tested have a trypsin (N.T.) equivalence (by the fibrinolytic test) of less than 1:40,000. This is equivalent to .025 mg. N.T., or 1.06×10^{-4} $[T.U.]_{\mathrm{m}}$, per c.c. Comparison with dog, human, and other plasmas will be deferred for a subsequent communication, but it may be stated that the *rabbit* data are significantly lower than in carnivorous species. This offers a rational explanation of the exceptional stability and enzyme-free character of Parfentjev's "rabbit clotting globulin," which makes it so excellent a thrombin for the assay test and other purposes.

Owing to the relative paucity of serum-tryptase, rabbit blood behaves somewhat differently from dog blood, in clotting experiments, under conditions similar to those employed by Tagnon.[15]

COAGULATION TESTS

Room temperature = 23° ± 2° C. Clotting-times for 1.0 c.c. weak fibrinogen solution *plus* 0.5 c.c. chloroform-treated materials. Character of clot (in parenthesis, Table II): ++ = complete (tube invertible); + = incomplete. The significance of the experimental data may be interpreted as follows:

1. When plasma is shaken with $CHCl_3$ and the tryspin-inhibitors thereby "neutralized," small amounts of serum-tryptase are activated. By its *thromboplastic action*,[16, 4] notwithstanding depression of the Ca-ions due to the citrate present, the enzyme activates a part of the prothrombin to thrombin. This increases to a low "peak" level and then decreases. We do not wish, at this time, to discuss the several possibilities which might account for the later decrease, but adsorption on fibrin, "immediate" anti-thrombins (i.e. "metathrombin" formation) and progressive thrombinolysis may be mentioned. The persistence of such a weak thrombin at all shows that tryptic thrombinolysis is negligible. Considerable unaltered prothrombin persists in the $CHCl_3$-treated plasma, as shown by (5-minute) recalcification of a sample and adding to fibrinogen, when solid clotting occurs in eight minutes. The recalcification produces no clot in the $CHCl_3$-plasma itself; neither does added thrombin, thus showing that the fibrinogen has all disappeared. It is, in fact, deposited as a fibrin coagulum (flocculant) adjacent to the chloroform layer in bottle A. No such appearance is seen in B — E. The thrombin formed by the tryptase action is sufficient to account for the fibrin deposit. The clots in the tests with

fibrinogen, although incomplete, were perfectly stable for three days. The important conclusion is that serum tryptase, in amounts too small to be detected by any of its other actions (viz., lysis of fibrin or thrombin, or their precursors) is, nevertheless, able to exert the typical thromboplastic action in the conversion of prothrombin to thrombin.

2. In recalcified plasma, thrombin production proceeds in the *natural* manner but is doubtless aided by the thromboplastic action of small quantities of tryptase liberated by the $CHCl_3$-treatment. This might not be true if the conversion of prothrombin to thrombin were completed prior to the addition of chloroform. In the present experiment, however, the conversion was definitely retarded and for an unusual reason, namely, too great an excess of Ca, occasioned by the inadvertent use of stock (N/2) instead of the customary (N/10) $CaCl_2$. Thus the preliminary plasma clotting required twenty minutes, instead of three minutes noted on repetition with N/10 $CaCl_2$. Thinking that the experiment might be instructive, the first sample was chosen for the $CHCl_3$ treatment and it did yield the pertinent observation that additional thrombin continued to form during the twenty-four hours of contact of the serum with chloroform. No evidence of tryptic thrombinolysis was obtained. The fibrinolytic test proves the paucity of tryptase, but the assay is definitely positive and in the clotting-test there was enough enzyme to produce clot retraction in three and one-half hours and the clot had almost lysed by the end of the third day, when observation was discontinued.

3. The addition of enzyme-free thrombin to citrated plasma produces complete conversion of fibrinogen to fibrin and unequivocal liberation of tryptase (see lytic tests). There is no evidence of any *immediate* thrombin formation from the plasma prothrombin. The slight excess of added thrombin is sufficient to account for the weak (60-minute) clot after the one-hour $CHCl_3$ treatment. By the end of six hours no thrombic activity is left, probably owing to destruction by the tryptase formed. After twenty-four hours a (weak) thrombic action reappears. This is attributed to the slow thromboplastic action of the enzyme on the prothrombin of the serum. That an abundance of prothrombin persists unaltered in the serum is clearly shown by a test in which a (30-minute) recalcified sample of the twenty-four-hour serum clots a test fibrinogen solidly in eighty *seconds*. The lytic tests reveal the small quantity of tryptase responsible for these effects. Retraction of the weak original clots, (*A*) and (*C*), occurred on the second day but lysis was far from complete by the end of the third day.

4. That well-washed fibrin contains traces of thrombin, which can be eluted with saline, is the basis for the old Gamgee-Howell method of thrombin preparation. The slight increase in the thrombin obtained after six hours is probably due solely to the longer period of extraction. Enzymic thrombinolysis may account for the falling off in thrombic activity in the twenty-four-hour sample. The persistence of such a weak thrombin in the presence of the serum tryptase revealed by the fibrinolytic tests is remarkable, however, and suggests that adsorption onto the fibrin protects the thrombin (to some extent) from the digestive action of small quantities of enzyme, which are obviously also adsorbed onto the fibrin clot and eluted with saline. The positive tests of *C* and

D show that the tryptase liberated by the $CHCl_3$ treatment is divided between the serum and the clot. Tagnon[15] was, therefore, well advised in shaking the *whole* clotting mixture with $CHCl_3$ in his fibrinolytic experiments and we propose to continue this practice in the clinical examination for human blood tryptase.

5. The serum experiments show a trace of persistent thrombin, which is to be expected in the absence of demonstrable tryptase activity.[6] The fibrin in the clotting tests was still solid after three days.

The close parallelism between tryptic and clotting activities, evident in these experiments, suggests an autocatalytic process of enzyme activation.

DISCUSSION

We should like to point out the undoubted confirmation, which Tagnon's[15] data afford, of the views expressed in frequent communications from the Michigan laboratories during the past three years. We have delayed full consideration of the role of serum tryptase in fibrinolysis because of a conviction that this is a minor and variable side-action of the role of the enzyme factor in blood-clotting. The present experiments with rabbit blood add emphasis to this view.

In evaluating the experiments of Eagle and Harris,[16] Tagnon is correct in pointing out that they compared crystalline trypsin to Ca + "thromboplastin" without attempting a definition of the latter term. Eagle's work must be credited with stimulating renewed interest in proteolytic enzymes and their relationships to blood clotting, although considerable older data appear in the literature and we must give a niche to the long-forgotten study of Collingwood and MacMahon, 1913,[17] suggesting a relationship of trypsin to progressive antithrombic action.

In extending Eagle's observations, Ferguson (op. cit.) has sought to demonstrate that the *natural* serum tryptase (long known to enzyme chemists) actually *is* the chief thromboplastic factor of the blood plasma. While it can act under conditions of not-too-great depression of the Ca-ionization as shown by Eagle,[16] Ferguson[3, 4] points out that Ca and cephalin are essential for optimal prothrombin activation. Particularly noted[3] in this connection is the "stability" of the clots obtained, which is a phenomenon again emphasized by Tagnon[15] in his rather obscurely presented view concerning "inhibitory" actions of "thromboplastin" (and "prothrombin"). Current studies of trypsin *inhibitors* are yielding very interesting data, which will appear from the Michigan laboratories in due course. That a deficiency of serum tryptase is the "bane of the Hapsburgs" is the Ferguson (1939)[9] theory of the causation of *hemophilia.*

SUMMARY

A new fibrinolytic method of protease (especially tryptase) assay is detailed. It can detect small differences within a range of (final) concentrations of 1:40,000 to 1:1,000,000 crystalline trypsin (1 mg. X. T. = 4.24×10^{-3} [T.U.] m.). While the wide fields of usefulness of the new methods are illustrated only at the extreme limit by the rabbit blood clotting experiments here pre-

sented, it is significant that this animal yields serum tryptase not in excess of 1:40,000 (N.T.) per cubic centimeter of materials tested and that appreciable quantities of enzyme liberation require coagulation(!) whether by added thrombin or by recalcification. With these relatively small amounts of enzyme (probably a species peculiarity), "thromboplastic" conversion of prothrombin to thrombin yields stable thrombin and stable fibrin clots.

EFFECT OF TOURNIQUETS ON VENOUS BLOOD SUGAR VALUES*

Winifred C. Loughlin, M.D., Herman O. Mosenthal, M.D., and
Ruth Halpern, B.A., New York, N. Y.

THE influence on the blood sugar level of a tourniquet employed to distend the veins in carrying out venepuncture has never been considered, and yet obvious possibilities exist.

METHODS

The present determinations were carried out, using a blood pressure cuff with mercury manometer attached as a tourniquet. A control series of observations was made without the use of a tourniquet. The tension applied to the upper arm was either above the systolic arterial pressure, "systolic tourniquet," or at or above the diastolic pressure, but distinctly below the systolic pressure, "diastolic tourniquet." Each one of the three procedures was carried out on five normal subjects in the fasting state. An interval of several days elapsed between each of the three experiments. The blood sugar determinations were carried out over a period of about six minutes.

The venous blood sugar estimations were made according to the method of Folin and Malmros[1] as modified for the photoelectric colorimeter by Saifer, Valenstein, and Hughes.[2] The determinations were carried out in duplicate on a carefully standardized photoelectric colorimeter.

TABLE I

CONTROL LEVELS OF BLOOD SUGAR MG. PER 100 C.C., CORRESPONDING TO CHART

	CASE 1	CASE 2	CASE 3	CASE 4	CASE 5
No Tourniquet	95	108	100	111	104
Arterial Tourniquet	88	98	84	102	89
Venous Tourniquet	81	93	99	125	103

RESULTS

The blood sugar series determined without a tourniquet serve as a control for the subsequent ones. The variations from the initial blood sugar in the 28 blood sugar estimations comprised in this group. varied above 6 mg. per 100 c.c. in only two instances: Case 2, 10 mg. below the control level, and Case 4, 10 mg. above the control level. From these results it may be concluded that changes of 10 mg. or less are within the limits of error for the present procedure.

The curves obtained when an arterial tourniquet was applied are distinctly more variable than when no tourniquet was used. In only three blood sugar estimations, however, did the changes exceed the 10 mg. limit set as the limit of error: 15 mg. per 100 c.c. deviation from the control in Case 2, and two values

*Sponsored by the New York Diabetes Association.
Received for publication, November 13, 1942.

of 11 mg. in Case 3. It would seem justifiable to conclude that the arterial tourniquet effects no very significant changes in the venous blood sugar; the greater variability of the blood sugar with the arterial tourniquet, as compared with the venous blood sugar values when no tourniquet was applied, may be ascribed to the time required to inflate the cuff, when for a few seconds the venous tourniquet would be active and induce such variations as are discussed in the next paragraph.

The results with the venous tourniquet are distinctly different. They show changes from the control blood sugar varying from 18 to 24 mg. per 100 c.c. In no case was the variation less than 18 mg. per 100 c.c.; in four instances the blood sugar rose; in one the principal change was a drop; the most consistent fluctuation was a rise in the blood sugar followed by a drop.

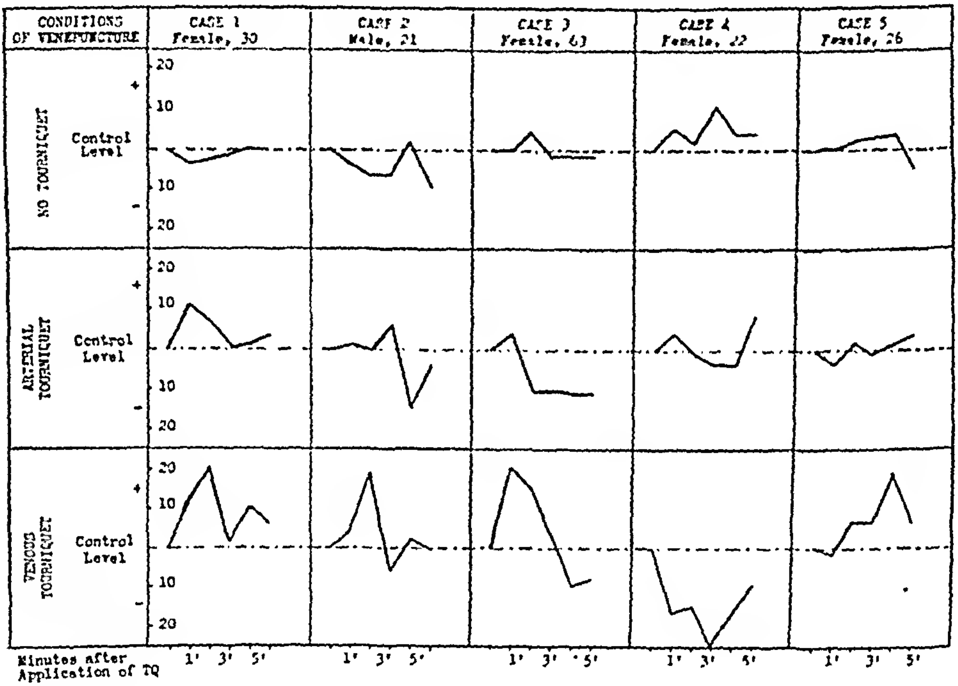

CHART I.—VARIATIONS OF THE VENOUS BLOOD SUGAR FROM THE CONTROL IN FASTING NORMAL SUBJECTS WITHOUT A TOURNIQUET, WITH AN ARTERIAL TOURNIQUET AND A VENOUS TOURNIQUET. RISE IN BLOOD SUGAR IS INDICATED BY THE HEIGHT OF THE CURVE ABOVE THE CONTROL LEVEL LINE, A DROP BY THE DEPTH OF THE CURVE BELOW THE CONTROL LEVEL LINE. THE CONTROL BLOOD SUGARS VARIED FROM 81 TO 125 MG. PER 100 C.C. SEE TABLE I.

DISCUSSION

Without a tourniquet the venous blood sugar level, obtained at minute intervals over a six-minute period, shows no variations that cannot be ascribed to the limit of error inherent in the procedure employed. The results after the application of a venous tourniquet indicate that some adjustments occur that will cause the blood sugar to undergo fluctuations that are significant from the clinical point of view. Such changes deviate about 20 mg. per 100 c.c. from the expected value; they generally take place within two minutes after the application of the venous tourniquet. As a rule there is a rise of the blood sugar,

though in one instance (Case 4) there was a marked fall. These initial variations in the venous blood sugar are transient, and are followed by a shift in the opposite direction after the tourniquet has been in effect two or three minutes.

The increase of the glucose concentration in the venous blood while a venous tourniquet is acting may be ascribed to the forcing of arterial blood with its higher sugar content into the occluded veins.

Ebert and Stead[3] have shown that one of the effects of venous tourniquets on the extremities is a reduction of the plasma volume in the blood vessels, resulting from a transudation of fluid into the surrounding tissues. Since the concentration of glucose is greater in the plasma than in whole blood, such a diminution of plasma volume would account for a lowering of the blood sugar when the amount of plasma was less and the red blood cell content was greater.

These two factors, increased accumulation of arterial blood in the veins and diminished plasma volume, occurring at different intervals after the application of a venous tourniquet, would account for either a rise or a drop in the venous blood sugar. The absence of these two influences with no tourniquet at all would explain the stabilization of the venous blood sugar under those circumstances.

Venous blood sugars determined after the application of an arterial tourniquet are slightly more variable than those when no tourniquet is used. This may be accounted for by the transient phase of venous tourniquet pressure in applying the arterial tourniquet. It is probable that if the tourniquet would be adjusted with great speed, the venous blood sugar figures derived from the use of the arterial tourniquet would duplicate those obtained without a tourniquet.

CONCLUSIONS

Without a tourniquet, the venous blood sugar levels remain constant over a period of five minutes. The application of a venous tourniquet results immediately in significant changes in the venous blood sugar amounting to 20 or even 25 mg. per 100 c.c. as either an increase or a diminution from the control value. The use of an arterial tourniquet causes some variations in the venous blood sugar, which, however, are much less marked than those obtained with the venous tourniquet. For the greatest accuracy a tourniquet should not be used in obtaining blood for venous blood sugar determinations.

AN APPARATUS FOR STORAGE OF GAS-FREE SOLUTIONS FOR USE WITH THE VAN SLYKE GASOMETRIC METHODS*

R. H. GOETZ,† M.D., CAPE TOWN, SOUTH AFRICA

VARIOUS apparatus have been designed to keep the reagents used for gasometric analysis gas-free for some length of time. Most of them, however, as pointed out by Guest and Holmes,[1] have the disadvantage that the alkaline solutions have to pass a glass stopcock,[2, 3] the grease of which does not

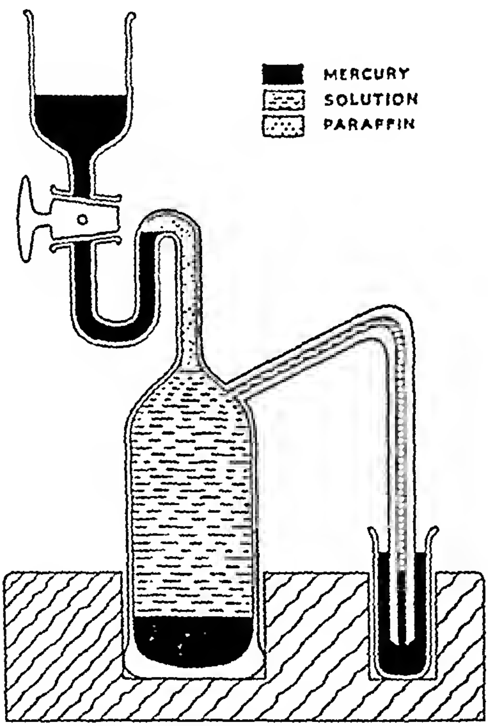

Fig. 1.

hold long against the alkaline solutions and leakages occur easily. The apparatus of Holmes[4] eliminates this difficulty, but it has the disadvantage of having to be made by an expert glass blower.

The following apparatus has been designed to take the place of more complicated pipettes; it has at the same time the advantage that only mercury or paraffin comes into contact with the stopcock.

*From the Department of Surgery, University of Cape Town.
†Jacobus Stephanus Marais Research Assistant.
The apparatus was blown for us by Mr. V. J. Hinkley.
I am indebted to the Government Grant Committee for a grant covering the expenses.
Received for publication, November 18, 1942.

As seen in Fig. 1, the vessel consists mainly of four parts: (1) the upper storage chamber for the mercury, (2) the lower storage chamber for the solution, (3) an S-shaped tube connecting both vessels and provided with a stopcock, and (4) a delivery tube which is immersed into a small test tube filled with mercury, providing the seal.

Filling of the Apparatus.—Before filling the vessel with the solution, it is filled with liquid paraffin, in which process special care has to be taken that the paraffin does not contain any air bubbles. Following this, the paraffin is displaced by the solution in the manner indicated in Fig. 2. The delivery tube is fitted into the bottom of the cup of the Van Slyke, a small rubber ring making

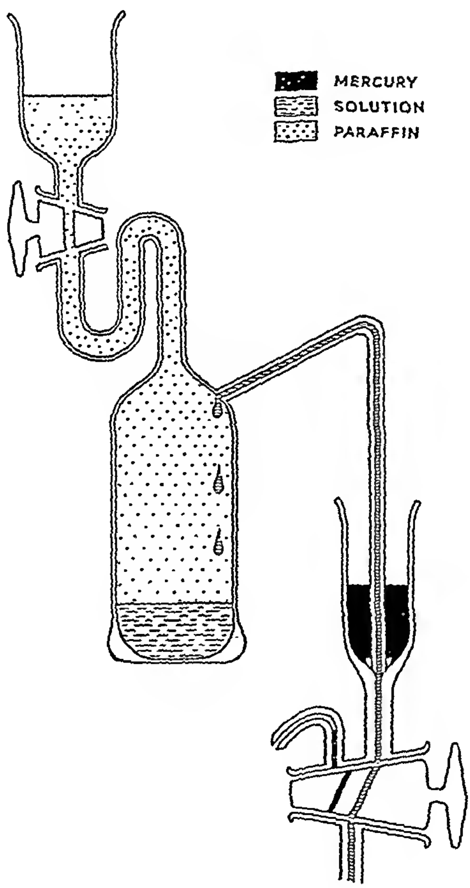

Fig. 2.

the connection airtight, and mercury sealing the connection as well. With the stopcock of our vessel open, and the leveling bulb of the Van Slyke in the upper ring, the upper cock of the Van Slyke pipette is opened and the gas-free solution is forced slowly up the delivery tube of our vessel. It then drops through the paraffin to the bottom of the storage chamber, displacing the liquid paraffin into the upper chamber of the vessel. The solution is thus collected in the storage chamber without coming into contact with the air. When all the solution has been delivered to the storage vessel, the stopcock of the vessel is closed, and the paraffin in the upper vessel is recovered. About 10 c.c. of mercury are

then poured into the upper chamber; part of it is allowed to fill the S-shaped connection, providing a seal. The vessel may then be placed in a convenient stand, its delivery tube being immersed into mercury as shown in Fig. 1. This provides a complete seal, and solutions have been stored gas-free in this way by us for many months.

The Use of the Apparatus.—In order to get the solution into the Van Slyke during an analysis, the upper storage chamber is filled with sufficient mercury. On opening of the stopcock, the mercury by its own gravity will flow from the upper into the lower storage chamber, displacing the solution via the delivery tube. After closing of the stopcock and after returning of the vessel into the stand, complete sealing is again obtained. Mercury has to be added from time to time in the upper vessel, as it is used for replacing the solution.

The dimensions of the apparatus can be clearly seen from the accompanying figures. Actually, any size for the vessel storing the solution is possible, but for practical purposes 100 c.c. capacity for the chamber holding the solution was found most suitable. The upper (mercury) chamber should conveniently hold about 30 c.c. in order to take the paraffin which is being displaced when filling, since 25 c.c. of solution may be made air-free at one time with the Van Slyke. The delivery tube is made of capillary tubing having a bore of 1.5 mm. It is constructed in such a way that the vertical part of it during filling and delivery of the solution is sufficiently far away from the cup of the Van Slyke as to allow smooth operation of the latter's stopcock.

SUMMARY

A self-sealing apparatus for the storage of gas-free solutions is described, which has the following advantages:

1. It eliminates the use of rubber parts and of glass stopcocks where the grease could be dissolved by the alkaline solution stored in the vessel.

2. It can be easily filled.

3. It provides a mercury seal for the delivery tube.

4. The apparatus is characterized by its simplicity and therefore can be easily made by a moderately experienced glass blower. It is much less liable to break than the more complicated vessels in use.

The vessel has been found most convenient, especially under such conditions where gasometric analyses are undertaken only at long intervals.

A RAPID MICROANALYTICAL METHOD FOR LEAD IN URINE*

SIDNEY KAYE,† SAN JUAN, PUERTO RICO

A METHOD is herein described for the rapid microanalysis of lead in urine. Aub and associates[1] mention the fact that ammonium hydroxide quantitatively precipitates lead as lead phosphate from urine. If such be the case, this would afford an excellent means of separating the lead from interfering organic matter in urine. Experimentation,[2] however, showed that excess ammonia did not result in a 100 per cent recovery. Fairhall[3] states that there is a 100 per cent precipitation of lead with ammonia at pH 10. This was found to be experimentally correct.

Several excellent procedures have been described for the destruction of organic matter in urine in preparation of the sample for the determination of lead. These employ either the dry muffle heat below 500° C. or the various acid oxidation modifications. Although fairly rapid, these methods are not as rapid as the phosphate precipitation. Moreover, in the wet oxidation methods, the quantities of urine analyzed have been so reduced that slight deviations become appreciable and significant when calculated on a liter or per diem basis. Larger samples of urine may, of course, be digested, but then there is time consumption in concentrating the volume.

PRINCIPLE OF METHOD

The method is based upon the total precipitation of lead by the addition of ammonium hydroxide to urine. Lead phosphate is very insoluble and is easily filtered out along with the alkaline earth phosphates of calcium and magnesium. This precipitate is subsequently dissolved with hot dilute nitric acid and is heated for a short time to oxidize any adhering organic material. Citric acid is added to keep the phosphates in solution during later neutralization, and potassium cyanide is added to form complex ions with interfering metals.** When the pH is adjusted between 9 and 10, the lead is extracted with dithizone†† to separate it from extraneous salts and interfering substances. Once the lead is separated, it is then split from the dithizone and titrated with standardized dithizone for an accurate determination. Under the above conditions only bismuth, tin, thallium, and lead react with dithizone. To remove the interference of bismuth and tin, these are previously extracted with dithizone while the solution is yet acidic. Lead is not extracted in this acid solution. Thallium, as a source of interference, has not been removed, but its occurrence is rare and unlikely.

††Dithizone is the abbreviated name for diphenylthiocarbazone.

Received for publication, Dec. 3, 1942.

REAGENTS

All solutions should be kept in pyrex glass bottles. Water is distilled from an all-pyrex still. Ammonia water and nitric acid should have low lead content.

Potassium Cyanide Solution: 10 Gm. of potassium cyanide (low in lead) dissolved in water to make 100 ml.

Citric Acid Solution: 200 Gm. of citric acid (low in lead) dissolved in water to make 500 ml.

Standard Lead Solution: 160 mg. of lead nitrate dissolved in 1,000 ml. of water. One milliliter is equivalent to 100 gamma* of lead.

Dithizone 1 for Preliminary Extraction: 25 mg. of dithizone dissolved in 400 c.c. of chloroform.

Dithizone 2 for Titration: 100 ml. of dithizone 1 diluted with 100 ml. of chloroform. This is standardized against known lead. Approximate value is 1 c.c. = 5 gamma lead. If kept in a brown bottle and in a cool place, the titer will not change for several months. This titer is satisfactory for amounts of lead near normal values. However, if larger amounts of lead are expected (this is determined approximately by the amount of dithizone required for the preliminary extraction), a stronger titer may be prepared. Dithizone 1, when standardized, is approximately 1 c.c. = 10 gamma lead. The titer should be calculated to at least one decimal unit.

All glassware should be of pyrex quality.

METHOD IN DETAIL

Description.—The total twenty-four-hour specimen of urine is collected and the volume measured. One-third of this volume is taken for analysis. A few drops of phenolphthalein and then dropwise ammonium hydroxide are added until the urine turns pink (pH 9 to 10). This is well shaken and stoppered and the precipitate which forms is allowed to settle for about thirty minutes. The precipitate is then separated by being filtered through a Buchner funnel with suction and refiltered if necessary. The precipitate is washed with several small portions of alcohol. The filter paper is then inverted so that the precipitate now faces the perforations of the funnel. Approximately 30 to 50 ml. of hot 3 per cent nitric acid are successively poured over the precipitate until it either dissolves or is completely transferred with the filtrate to the flask. This is more easily accomplished without suction. The total redissolved precipitate is then gently boiled for approximately twenty minutes. It is adjusted to a pH of from 3 to 3.5 (lower range of methyl orange) with the dropwise addition

*Gamma = 0.001 mg.

of ammonium hydroxide and transferred to a Squibb separatory funnel. It is then shaken out with 5 to 10 ml. of dithizone 1, and the dithizone-chloroform layer is discarded. This extracts and eliminates the possibility of either tin or bismuth appearing later as an interference. Lead is not extracted at this pH. Then 15 ml. of citric acid are added and the solution neutralized with ammonium hydroxide. With the addition of 2 ml. of potassium cyanide, the solution is ready for the lead extraction. In an ammoniacal solution and in the presence of potassium cyanide, dithizone has a selective affinity for lead, forming a cherry red complex of lead dithizone which is soluble in chloroform.

A small quantity of dithizone is run into the solution from a burette and vigorously shaken. The rapid appearance of a cherry red chloroform layer indicates the presence of lead. After each addition of dithizone, vigorous shaking is necessary and the colored chloroform layer is separated carefully and transferred to another separatory funnel. The last traces of lead dithizone are washed through with several small portions of chloroform. These are also collected and saved. The proximity of the end point (complete removal of lead) may be roughly estimated by the diminution of intensity of the cherry red color. If it is very red, a larger amount of dithizone may be added and again shaken and separated. After each shaking, the funnel is inverted and the stopcock opened to relieve the pressure. This is continued until all the lead has been extracted, which is indicated when further addition of dithizone does not impart a cherry red color to the chloroform layer, but on vigorous shaking a green color persists due to excess dithizone. The presence of many extraneous salts prevent a sharp end point (cherry red to green). Therefore, the first titration-extraction is not a reliable indication of the quantity of lead present. The end point is difficult to see because of the lag of the transition of colors (cherry red, pink, violet, blue, green). To rectify this, the several portions of extracted lead dithizone should be carefully collected and saved. These combined chloroform extracts are shaken with 15 ml. of 1 per cent nitric acid which quantitatively separates the lead into the aqueous solution. The green chloroform layer is discarded. The aqueous layer is washed by shaking with a fresh portion of chloroform to remove any residual dithizone. To the solution are added several drops of phenolphthalein and dropwise ammonia until alkaline, then 2 ml. of potassium cyanide, and lastly dropwise citric acid until the solution is just faintly pink. If the end point is overrun, a drop of dilute ammonium hydroxide will adjust it.

The solution is now titrated with standard dithizone 2. The dithizone may be added in one large portion to within 5 ml. of the total amount required in the first extraction (when cherry red color started to change). The separatory funnel is thoroughly shaken, allowed to stand until the layers separate, and the red chloroform layer is then removed. From this point, the titration continues carefully. The dithizone is delivered in successive small quantities (approximately 0.5 ml. portions), and it is necessary before each shaking to add approximately 1 ml. of chloroform so as to have enough volume to see the color. After each addition, the solution should be vigorously shaken, allowed to settle, and then the chloroform layer run out and discarded. This is continued until the end point is reached, which is a persisting light green color in the chloroform layer.

For standardization a known lead solution is titrated with the dithizone solution using the procedure previously described. Since the lead is in pure solution, the preliminary titration-extraction is not necessary. The quantity of lead in the standard used, divided by the number of milliliters of dithizone solution required, represents the dithizone lead equivalence.

A lead blank is determined for the reagents. However, since the reagents should be of highest quality or are previously deleaded, the blanks should be relatively low.

TABLE I

ANALYSIS OF 500 ML. PORTIONS OF POOLED URINE

LEAD ADDED (GAMMA)	TOTAL LEAD RECOVERED (GAMMA)	EVALUATION OF THE AMOUNT OF LEAD ADDED (GAMMA)
00	23	--
00	22	--
25	47	25
25	47	25
50	73	51
50	70	48
100	118	96
100	123	101
150	169	147
150	172	150
200	212	190
200	224	202
500	505	483

Table I indicates that this method for lead is applicable to urine, using dithizone as a standard solution. The maximum error was ±5 per cent.

SUMMARY

1. Excess ammonium hydroxide as prescribed by Aub and associates for the precipitation and absorption of lead is unsatisfactory.

2. The lead may be totally separated from urine at pH 10 as suggested by Fairhall.

3. The lead is quantitatively determined by an extraction-titration procedure with dithizone reagent.

4. This method for determining lead in urine is rapid, sensitive, and reliable, and the maximal deviation is ± 5 per cent.

PROGRESS

THE VERIFICATION TEST IN THE SEROLOGY OF SYPHILIS*

REUBEN L. KAHN, D.SC., ANN ARBOR, MICH.

INTRODUCTORY

1. *The Verification Test—The Search for Characteristics Which Differentiate Specific From Nonspecific Serologic Reactions.*—Studies in progress in this laboratory aimed at the detection of differential characteristics of true and false positive serologic reactions have thus far led to two observations which have afforded a basis for several practical procedures. The observations are that, within certain limits, (1) specific serologic reactions tend to become stronger and nonspecific reactions weaker as the reacting temperature is increased; and (2) specific serologic reactions tend to become stronger and nonspecific reactions weaker as the salt concentration of the reacting system is increased. The practical procedures are (1) differential temperature technique, (2) triple quantitative technique, and (3) salt dispersibility technique.

2. *Occurrence of Biologic False Positives.*—The nature of biologic false positive reactions is still obscure. It is believed that the following two factors largely determine the occurrence of these reactions with serodiagnostic tests: (1) a tendency to give such reactions on the part of certain individuals, and this tendency may be constitutional in nature; and (2) some pathologic disturbance (fever, cancer, etc.) or biologic imbalance (pregnancy, vaccination, etc.) serving as the immediate cause of such reactions, although the reactions are encountered also in individuals apparently free from pathologic disturbance or biologic im-

*From the Clinical Laboratories, University of Michigan Hospital. Aided by a grant from the United States Public Health Service.

This article is not a review on false positives and their detection. The article considers only the present status of the verification test. The experimental studies upon which this article is based were carried on in this laboratory in association with Elizabeth B. McDermott, Jacob Adler, Stanley Marcus and other members of the staff, and will be published elsewhere.

balance. The occurrence of positive reactions in the absence of syphilis is unique *in that many individuals who show no tendency to give these reactions* with serodiagnostic tests begin to give them with the increase in the sensitivity of the tests, indicating that seronegative persons possess latent potentialities for manifesting such reactions.

3. *Relation Between Biologic False Positives and Serologic Reactions Given by Lower Animals.*—Studies carried out in this laboratory indicate that false positive reactions given by human beings and the positive serologic reactions given by pigs, horses, rabbits, and other animals possess similar characteristics. Thus, these two types of reactions are most marked (1) when the tests are performed at cold temperature (1° C.), and (2) when the salt concentration of the reacting system is reduced to a minimum. These findings suggest that a close relationship exists between human and animal reactions of nonsyphilitic origin given by serodiagnostic tests. In this laboratory, indeed, animal sera are commonly used for studies of false positive reactions.

4. *Basis of Biologic False Positives.*—Tissue extract antigens of excessive sensitivity can be prepared which will give about 40 per cent of positive serologic reactions in nonsyphilitic persons. If the serologic tests with excessively sensitive antigens are performed at cold temperature, the nonspecific sensitivity can be raised to about 80 per cent. If the tests with excessively sensitive antigens are performed at cold temperature with unheated sera (instead of with sera heated for 30 minutes at 56° C.), the nonspecific sensitivity reaches about 98 per cent. Certain lower animals (horses, pigs, chickens) also give 100 per cent of positive reactions when the tests are performed under the same conditions. These findings suggest that there exists a "universal" serologic (nonsyphilitic) reaction, given by human beings and certain lower animals, which is best manifested under conditions of low temperature. It was shown before that the biologic false positive reaction given by serodiagnostic tests is similarly best manifested under conditions of low temperature. Hence, it would seem reasonable to assume that the two reactions are related to one another and that the universal reaction may be the basis of biologic false positives.

5. *Biologic False Positives in the Presence of Syphilis.*—Biologic false positives may be given by persons with syphilis. Thus, a certain person has a tendency to give false positives, let us say, when he contracts a cold. In due time, he becomes infected with syphilis and he begins to give specific reactions. Then, when he contracts a cold, he is likely to give at the same time both specific and nonspecific reactions. Should he become specifically seronegative following therapy, he will give only the nonspecific reaction when from time to time he has a cold. Also, certain neurosyphilitic patients treated with malaria give specific serologic reactions before malarial therapy, both specific and nonspecific reactions soon after the therapy, and in due time only specific serologic reactions again.

6. *Technical and Biologic False Positives.*—False positives are generally classified as either technical or biologic, but it is not always possible to draw a line of demarcation between them. A false positive given by a supersensitive test, for example, may be interpreted by some as technical, because the antigen

in this test shows a tendency to give, let us say, 5 per cent of false positive reactions. But the fact that 5 particular persons in 100 gave these reactions would indicate that the sera in these persons differed biologically (biochemically or physiochemically) from the sera in the remaining 95 persons, thereby rendering these reactions biologic false positives. Experience indicates that any serodiagnostic reaction suspected of being a false positive, whether biologic or technical, may be investigated with the verification test.

7. *Verification Results and Clinical Findings.*—The dependability of laboratory results in a given infection is generally determined by the extent to which these results are corroborated by clinical findings of that infection. Unfortunately, verification reports of false positives cannot be corroborated by a definite clinical indicator. Negative clinical findings of syphilis represent *the* clinical indicator of false positives, and negative findings cannot have the same value as positive findings. Yet, in the diagnosis of false positives, the establishment of negative clinical findings of syphilis is obviously of first importance. When such findings corroborate verification results of false positives, the significance of these results immediately becomes fortified, just as the significance of positive Widal reactions becomes fortified by clinical findings of typhoid fever. The verification test, like other laboratory methods of an immunologic nature, does not lend itself to mass testing. Even with serodiagnostic tests having a record of use for over a generation, mass testing is acceptedly wrought with difficulties. Briefly, in the application of the verification test to the detection of a false positive reaction in a given case, it is assumed that thorough search for clinical evidence of syphilis had led to negative findings and that the examining physician had concluded that the patient was most likely free from syphilis. A verification report of a false positive reaction in a case such as this may thus be said to be corroborated by clinical findings.

THE "TYPING" OF SERODIAGNOSTIC REACTIONS

8. *Reporting Verification Results to Physicians.*—The function of the verification test is to type positive serodiagnostic reactions on the basis of their specificity. Hence, the results of the verification test are reported not as positive or negative, but only in respect to the specificity of the serodiagnostic reactions. To illustrate: (1) A physician receives a report of a positive serodiagnostic reaction in a given case. (2) He believes this reaction to be a false positive and requests a verification test. (3) The verification test determines whether the serodiagnostic reaction shows characteristics of a luetic type or of a nonluetic type of reaction or perhaps of both types.

9. *Types of Serodiagnostic Reactions Encountered With Verification Test.*—(1) "General biologic (nonluetic) type"* is the designation employed when, according to the verification test, a serodiagnostic reaction shows characteristics of a false positive. (2) "Type of reaction similar to that obtained in lues" is the designation employed when, according to the verification test, a serodiagnostic

*This designation, it is believed, is more desirable than the purely negative designation of "false positive," since in addition to indicating absence of syphilis it indicates the presence of a reaction which in many instances accompanies a pathologic disturbance or biologic imbalance. The term "general biologic" is being employed because of the biologically widespread nature of this reaction, especially among lower animals. The term we believe is also preferable to "biologic" in designating false positives, since syphilitic reactions or "true positives" are also biologic reactions.

The terms "lues" and "luetic" are employed instead of syphilis and syphilitic because the latter terms are too obvious to the laity.

reaction shows characteristics of a syphilitic reaction. (3) "Negative type" is the designation employed when the results of the verification test are negative. (4) "Inconclusive" is the term used when the verification results are atypical. (5) Occasionally, a positive serodiagnostic reaction embodies, according to the verification test, both the syphilitic and nonsyphilitic types of reactions.

10. *Procedures of the Verification Test.*—(1) The triple quantitative technique, described later, is employed in typing strongly positive (++++) serodiagnostic reactions on the basis of their specificity. Three types of reactions are generally encountered: the luetic type, the general biologic type, or a combination of both types. (2) The differential temperature technique, also described later, is employed in the typing of moderately and weakly positive (+++, ++, + and ±) serodiagnostic reactions. Here also three types of reactions are generally encountered: the luetic type, the general biologic type, and a combination of both types. (3) The salt dispersibility technique, due to its simplicity, is employed with all sera. (4) The standard Kahn test and a modified Kahn procedure (Method B) are also employed in performing verification tests.

THE VERIFICATION TEST IN KNOWN CASES OF SYPHILIS

11. *The Verification Test in the Various Stages of Syphilis.*—The vast majority of syphilitic cases give the luetic type of reaction with the verification test; a relatively small number give both the luetic type and the general biologic type. In a small percentage of cases of early syphilis, only the general biologic type of reaction may be encountered. In repeated examinations, as the serologic reaction becomes stronger in this stage of syphilis, the luetic type of reaction is obtained. This temporary occurrence of the general biologic type of reaction in early syphilis must be kept in mind when this type of reaction is reported in a case in which there is the slightest possibility of the presence of early syphilis. Repeated verification tests at intervals of a week or more are necessary. These tests will indicate the trend of the serodiagnostic results and will determine whether the general biologic type of reaction persists. In the various stages of syphilis other than early syphilis the luetic type of reaction is generally obtained.

12. *The Verification Test in Treated Cases of Syphilis.*—The common reaction obtained is of the luetic type. Occasionally, the general biologic type is obtained. Preliminary studies of verification reactions in treated cases have led to several observations which promise to prove of clinical value. Thus: (1) The general biologic type of reaction is occasionally encountered following treatment, in addition to the luetic type, in persons who presumably show a tendency to give the former type of reaction under conditions of pathologic disturbance. It is believed that the toxic effect of the antisyphilitic treatment may result in sufficient pathologic disturbance as to be the immediate cause of the general biologic type of reaction. If so, it is reasonable to assume that a higher degree of toxicity will call forth this type of reaction to a greater extent than a lower degree of toxicity. The verification test may thus indicate variations in toxicity of different methods of therapy. (2) The verification test in certain seropositive treated cases is capable of indicating in advance that they will in due time become seronegative. This finding is based on the

observation that the formed precipitates in verification reactions show a change in stability as these cases begin to approach seronegativity. The precipitates, at first stable and indispersible, become unstable and dispersible. The tendency toward dispersibility may become manifested weeks or months before seronegativity is reached. This capability of the verification test to indicate seronegativity in advance may be of value in the study of the efficacy of various methods of therapy. (3) The verification test in certain serologically fast cases following adequate therapy may establish that the reactions are not of the luetic type but of the general biologic type.

THE VERIFICATION TEST IN SERONEGATIVE CASES

13. *The General Biologic Type of Reaction in Seronegative Cases.*—Some persons who are clinically free from syphilis and who give negative serodiagnostic reactions, nevertheless give the general biologic type of reaction with the verification test. Indications are that these persons are "carriers" of false positives. They may be seronegative with one test but seropositive with another. Or they may be seronegative today and seropositive a week later. Then again, some nonsyphilitic persons, negative with serodiagnostic tests, are positive with supersensitive tests. Verification studies of persons giving negative serodiagnostic reactions reveal three main groups: (1) those giving the negative type of reaction, (2) those giving the general biologic type, and (3) a very small group of treated cases of syphilis giving the luetic type of reaction.

THE VERIFICATION TEST IN CASES IN WHICH FALSE POSITIVES ARE SUSPECTED

14. *Routine Applicability of Verification Test to Cases in Which False Positives Are Suspected.*—Experience gained with the verification test during the past several years indicates that the greatest value of the test lies in the investigation of the specificity of positive serodiagnostic (precipitation or complement fixation) reactions in such cases in which all clinical indications point to the absence of syphilis. When the verification test is applied to such cases, the general biologic type of reaction may be said to corroborate clinical findings, while the luetic type of reaction may be said not to corroborate clinical findings. It is with this view in mind that the interpretation of these two types of reactions is considered.

15. *Interpreting the General Biologic Type of Reaction.*—A single report of a general biologic (nonluetic) type of reaction can be interpreted as a false positive with reasonable safety, provided the donor gives a history of fluctuating or weak serodiagnostic reactions extending for some weeks or months; in the face of strongly positive serodiagnostic reactions, repeated verification studies are indicated to make sure that the results are persistently of the general biologic type. A general biologic type of reaction in the absence of a serologic history (i.e. when a person gives a positive serodiagnostic reaction presumably for the first time) should be checked preferably in a week or two before establishing a diagnosis of a false positive.

16. *Interpreting the Luetic Type of Reaction.*—A luetic type of reaction obtained in a case in which clinical indications point to a false positive requires additional clinical studies and repeated verification tests. In our experience, these

clinical and verification studies have led to the establishment of syphilis in most instances. In a few instances clinicians have expressed the belief that they were dealing with false positives in spite of persistent verification reports of the luetic type of reaction. A transient luetic type of reaction has been observed in an isolated nonsyphilitic case of postinfection or postvaccination, the reaction becoming of the general biologic type in the course of some weeks. Weakly positive serodiagnostic reactions, which according to the verification test are of the luetic type, are especially difficult to interpret. Repeated examinations at prolonged intervals are often necessary before a final diagnosis can be established.

PROCEDURES

1. Triple Quantitative Technique

Applicability.—This technique is applicable to sera which give strongly positive (++++) serodiagnostic (complement fixation or precipitation) reactions suspected of being false positives.

Technique.—The technique involves the use of three quantitative Kahn procedures: in the first, the serial dilutions of serum are made with distilled water; in the second, the serial dilutions are made with 0.9 per cent sodium chloride solution, and in the third, the serial dilutions are made with 2.5 per cent sodium chloride solution. Dilution ratios of 1:5, 1:10, 1:20, 1:30, 1:40, and 1:50 are generally ample. Standard Kahn antigen suspension (prepared with 0.9 per cent salt solution) is used in 0.025 c.c. amounts, and each of the serial dilutions of serum in 0.15 c.c. amounts. After permitting the serum-antigen mixtures to stand for three to five minutes, the tubes are shaken for three minutes in the usual manner. Distilled water or salt solution of the concentration corresponding to that used in the serial dilutions of serum is then added to the tubes in 0.5 c.c. amounts; after agitating the tubes for about ten seconds to mix the ingredients, the precipitation results are read.

Results.—Known syphilitic sera generally give a higher quantitative titer with the serial dilutions of serum with 2.5 per cent salt solution than with 0.9 per cent salt solution (luetic type of reaction). Known nonsyphilitic sera generally give a higher quantitative titer with the serial dilutions of serum with 0.9 per cent salt solution than with 2.5 per cent salt solution (general biologic type of reaction).

The quantitative titer with the serial dilutions of serum with water throws additional light on the type of the reaction in question. Thus, this titer in a luetic type of reaction is lower, and in a general biologic type of reaction is higher, than the titer with 0.9 per cent salt solution, unless both the luetic and general biologic types of reactions are present. Then, the titer with the serial dilutions of serum with 0.9 per cent salt solution is lower than either with water and with 2.5 per cent salt solution. Table I presents typical reactions given by the triple quantitative technique.

Note.—Sera of low quantitative titer are also examined in this laboratory with the differential temperature technique. The sera are first diluted with an equal amount of 0.9 per cent salt solution or with half the amount (depending on the quantitative titer given by the serum) before employing the differential temperature technique.

2. Differential Temperature Technique

Applicability.—This technique is applicable to sera giving moderately and weakly positive (+++, ++, + and ±) serodiagnostic (complement fixation or precipitation) reactions, suspected of being false positives.

Technique.—(1) Kahn racks with test tubes are placed in a 37° C. water bath for fifteen minutes before performing the tests. The pipettes necessary in performing the test are kept at 37° C.* (2) The serum is heated for thirty minutes at 56° C. and is then placed in the 37° C. water bath for fifteen minutes before using. (3) Standard Kahn antigen is mixed with salt solution at room temperature in the usual manner according to the titer, and the antigen suspension is immediately transferred to a Kahn tube and placed in the water bath for

fifteen minutes. (4) The amounts of antigen suspension (0.05, 0.025, and 0.0125 c.c.) are then deposited at the bottom of the Kahn tubes, followed by the serum (in 0.15 c.c. quantities), and the mixtures shaken for ten seconds without removing the rack from the water bath. The rack remains in the bath for ten minutes and is then shaken for three minutes at room temperature. (5) Physiologic salt solution kept in a 37° C. water bath is then added to each tube in the usual amount (1, 0.5, and 0.5 c.c.); the tubes are agitated sufficiently to assure proper mixing and the results are read immediately. (6) A microscope mirror or a slit lamp is used in the reading of results.

*Specially constructed water baths for this technique are supplied by A. S. Aloe Co., St. Louis.

The technique at 1° C. requires a refrigerated bath at 1° C., and if not available, an ice water bath with chopped ice. The steps in the technique as carried out in the 37° C. water bath are applied to the technique in the 1° C. water bath. The temperature of the serum and antigen suspension is brought to 1° C., and the serum is added to the antigen suspension and mixed at this temperature. Tests performed at 1° C. require special care in reading the results due to the film of moisture condensed on the outside of the tubes. This film disappears by dipping the tubes in a solution of cold alcohol. Not more than ten tests should be carried out at any one time, either at warm or cold temperatures.

Results.—Syphilitic sera generally give more marked precipitation at 37° C. than at 1° C. (luetic type of reaction), while nonsyphilitic sera generally give more marked precipitation at 1° C. than at 37° C. (general biologic type of reaction). Typical illustrations of these types of reactions are presented in Table II. It is noted that similar precipitation results at all temperatures are considered as inconclusive.

3. Salt Dispersibility Technique

Technique 1.—When applied to weakly positive sera suspected of giving false positive (precipitation or complement fixation) reactions.

Procedure: A 30 per cent solution of sodium chloride of "reagent" quality is employed in this technique. The standard Kahn test is performed and the

results read in the usual way after the addition of 0.9 per cent salt solution to each tube. Immediately, 0.15 c.c., 0.1 c.c., and 0.1 c.c. of the 30 per cent salt solution are added, respectively, to the three tubes; the rack is then shaken by hand for fifteen seconds, placed in the 37° C. water bath for five minutes, again shaken for fifteen seconds, and the results read.

Results.—In the case of syphilitic sera, the precipitates are generally either the same as before the addition of the concentrated salt solution or they are more pronounced. In the case of nonsyphilitic sera, the precipitates become dispersed and the results appear negative. Table III presents typical reactions given by the salt dispersibility technique.

Technique 2.—When applied to all sera suspected of giving false positives and to the several verification techniques.

Procedure: Due to the simplicity of the dispersibility technique, it is being applied in this laboratory to the triple quantitative and differential temperature techniques in addition to its application to the standard Kahn technique. Thus, after reading the results of the triple quantitative technique, 0.1 c.c. of 30 per cent salt solution is added to each tube showing a precipitate, shaken fifteen seconds, incubated at 37° C. for five minutes, again shaken for fifteen seconds, and the final results read. Similarly, after reading the results of the differential temperature technique, 0.15 c.c., 0.1 c.c., and 0.1 c.c. of the 30 per cent salt solution are added, respectively, to each set of the three tubes showing precipitates and the test is completed as in Table III.

Results.—As a general rule, precipitates in nonsyphilitic reactions become dispersed on the addition of the 30 per cent salt solution, while precipitates in syphilitic reactions do not become dispersed. In early syphilis and in highly treated cases of this disease, dispersibility of the precipitates may be noted. But in the absence of clinical indications of syphilis, the dispersibility of precipitates indicates false positive reactions.

Discussion of results.—(1) *Dispersibility technique applied to four plus Kahn reactions.* A definite relationship exists between the strength of nonspecific serologic reactions and the concentration of salt solution required for the dispersion of precipitates. Since different four plus reactions may be of different quantitative titers, the precipitates in such reactions may require different salt concentrations for their dispersion. In the case of nonsyphilitic sera of high titer, precipitates which are not dispersed in the standard Kahn test by the usual dispersibility technique will often disperse by a second addition of 0.15 c.c., 0.1 c.c., and 0.1 c.c. of 30 per cent salt solution to the tubes. In some instances even this second amount of concentrated salt solution will not disperse the precipitates of the strongly positive reactions. Hence, nondispersibility of the precipitate in a strongly positive reaction cannot by itself be interpreted as a syphilitic type of reaction. The dispersibility of the precipitate is a common property of weak nonsyphilitic reactions and is occasionally noted also in nonsyphilitic reactions of high titer.

(2) *Dispersibility technique applied to the triple quantitative procedure.* Generally precipitates in syphilitic sera do not disperse on the addition of 30 per cent salt solution. Now and then a serum is encountered which gives a higher quantitative titer in the serum dilutions with 2.5 per cent salt solution than in the serum dilutions with 0.9 per cent solution (suggesting a luetic type of reac-

tion), but which shows dispersible precipitates in all tubes on the addition of the 30 per cent salt solution. It is believed that such dispersibility is strongly suggestive of a false positive reaction. In instances in which only the precipitates in the highest serum dilutions show dispersibility while the precipitates in the low serum dilutions do not show dispersibility, the reactions are generally of the syphilitic type, noted particularly in treated cases.

(3) *Dispersibility technique applied to the differential temperature procedure.* Dispersibility of precipitates in reactions obtained at 37° and 1° C. is the common picture presented by false positives. In syphilitic cases, the precipitates are generally not dispersed in reactions obtained at 37° C. but are dispersed in reactions obtained at 1° C., although they may not be dispersed also in the latter reactions.

4. Method B

Method B consists of performing the standard Kahn test as usual with the exception that, after the three-minute shaking period, sodium chloride solution of 2.5 per cent concentration instead of 0.9 per cent is added to the tubes in the regular amounts of 1.0, 0.5, and 0.5 c.c., respectively. When this method is applied to doubtful serodiagnostic reactions, it is frequently observed that in nonluetic cases the results are weaker than those given by the standard Kahn test, while in luetic cases the results are the same or stronger.

5. Combined Use of the Several Verification Techniques in Practice

When a blood specimen reaches this laboratory for a verification test, the serum is separated from the clot in the usual way, checked for clarity, heated for thirty minutes at 56° C., rechecked for clarity, and within about ten minutes after the heating period, the following preliminary tests are performed:

1. *The standard Kahn test.*

2. *Method B,* which consists of the standard Kahn test, in which the diluent added to the tubes after the three-minute shaking period (1.0, 0.5 and 0.5 c.c.) consists of 2.5 per cent salt solution instead of 0.9 per cent.

3. *Salt dispersibility technique.* The results of the above two tests are read and recorded, and without waiting fifteen minutes for rereading, 0.15 c.c., 0.1 c.c., and 0.1 c.c. of 30 per cent sodium chloride solution are added respectively to the three tubes of each test, shaken fifteen seconds, placed for five minutes in a 37° C. water bath and for two to three minutes at room temperature, shaken again for about fifteen seconds and the results read and recorded.

The results of the above three tests are taken into consideration before proceeding with the additional techniques.

In the case of weakly positive reactions: If Method B gives weaker results than the standard Kahn test, it is indicative of a false positive reaction; and in such a case, the salt dispersibility technique will lead to dispersion of the precipitates and to negative results. The differential temperature technique is then performed for confirmation and is likely to give a nonluetic type of reaction. If Method B gives results which are the same or stronger than those of the standard test, the precipitates are generally not dispersible and the differential temperature technique is likely to give a luetic type of reaction. The application of the dispersibility technique to completed differential temperature reactions commonly gives additional confirmation of either the luetic or nonluetic types, as the case may be.

In the case of strongly positive reactions: The results of the standard Kahn test and of Method B are equally four plus and the precipitates may or may not be dispersed by the concentrated salt. The triple quantitative technique is then performed, the results read, and the salt dispersibility technique applied to the completed reactions. Typically nonsyphilitic patterns with the triple quantitative technique are generally confirmed by complete dispersion of the precipitates. Inconclusive patterns with the triple quantitative technique which show dispersibility of the precipitates indicate nonsyphilitic type of reactions. Rarely one encounters a syphilitic pattern in which the precipitates become dispersed. It is believed that in such instances (in the absence of clinical evidence of syphilis) the reaction is in all probability of the nonluetic type.

In the case of negative reactions: The differential temperature technique is employed to determine if a reaction is obtained at 1° C., generally given by "carriers" of false positives, or at 37° C., occasionally obtained in highly treated cases of syphilis.*

AN EXPLANATORY STATEMENT TO PHYSICIANS ON VERIFICATION REPORTS

In this laboratory, the following statement on interpretation is submitted to physicians with each verification report:

The verification test is a supplementary procedure to serodiagnostic tests; its function is to "type" positive serologic (precipitation or complement fixation) reactions on the basis of their specificity; in practice, the test is applicable to cases in which physicians suspect false positive reactions with complete lack of clinical indications of syphilis.

1. "*Type of reaction similar to that obtained in lues*" is reported when, according to the verification test, the positive serodiagnostic reaction shows characteristics of a specific reaction. This type of reaction is commonly noted in known cases of syphilis.

2. "*General biologic (nonluetic) type of reaction*" is reported when, according to the verification test, the positive serodiagnostic reaction shows characteristics of a false positive. This type of reaction is commonly noted in nonsyphilitic cases.

(1) *General biologic (nonluetic) type of reaction in seronegative cases.* Certain nonluetic persons, although giving negative reactions with serodiagnostic tests, may give the general biologic type of reaction with the verification test. These persons are looked upon as potential "carriers" of false positive reactions, giving such reactions off and on with serodiagnostic tests and more frequently with supersensitive tests.

(2) *General biologic (nonluetic) type of reaction in treated cases of syphilis.* Persons who have a tendency to give false positive reactions may exhibit the same tendency after they contract syphilis, and the verification test will then demonstrate the presence of both the luetic and general biologic types of reactions. Following therapy, as these persons are approaching seronegativity, they may give the general biologic type only.

3. "*Negative type*" is reported when the results of the verification test are negative. This type of reaction usually accompanies negative serodiagnostic reactions.

4. "*Inconclusive*" is reported when the verification results are atypical.

5. *Exceptions:*

(1) In isolated instances, physicians have claimed nonspecificity for a given positive serodiagnostic reaction in spite of persistent verification findings of the luetic type.

(2) Transient reactions of the luetic type have been observed in a small percentage of seropositive (nonluetic) cases following infection or immunization.

(3) Transient reactions of the general biologic type have been observed in a small percentage of known cases of early syphilis.

---

*Studies of the verification test with supersensitive antigens will be reported at a later date.

Interval retesting. Whenever verification results do not conform to clinical opinion or whenever there is a question of the diagnosis of early syphilis, it is of importance to repeat the verification test at intervals of weeks instead of days. Interval retesting will establish the serologic trend in questionable cases with far greater dependability than immediate retesting.

SUMMARY

Nonspecific and specific serologic reactions show similar characteristics with modern serodiagnostic (precipitation and complement fixation) tests for syphilis; hence, these tests do not offer a practical means for the detection of false positives in routine serologic practice. Studies carried out in this laboratory on differential characteristics of nonspecific and specific serologic reactions led to the observation that these reactions have different temperature and electrolyte requirements for optimal reactivity. This observation, in turn, led to the development of several procedures capable of determining whether certain serodiagnostic reactions possess characteristics of specific or nonspecific reactions, or of both types of reactions. These procedures (termed verification test) "type" serodiagnostic reactions on the basis of their specificity and are of practical value, especially when applied to the typing of seropositive cases that are free from clinical indications of syphilis. When applying the verification test to such cases, nonluetic type of reactions may be looked upon as being corroborated by clinical opinion, and the diagnosis of "false positive" can then be made with reasonable certainty.

CLINICAL AND EXPERIMENTAL

THE PRODUCTION OF CHRONIC HYPERTENSION IN DOGS BY PROGRESSIVE LIGATION OF ARTERIES SUPPLYING THE HEAD*

H. R. Fishback, Sc.D., M.D., Frank E. Dutra, M.S., M.D., and Edwin T. MacCamy, M.S., M.D., Chicago, Ill.

THE puzzle of the etiologic relationships of high blood pressure has provided the impetus for quite varied and extensive research. The trend of this work has changed through the years, but there have been two conditions under investigation quite constantly; namely, arteriosclerosis and kidney disease.

While arteriosclerosis is commonly found with chronic hypertension, it is not invariably demonstrable. Furthermore, there may be quite extensive sclerosis, especially of the large vessels, without elevation of the blood pressure. Sclerosis of arterioles has been stated to be quite generally present in chronic hypertension. Gull and Sutton[1] believed this to be the essential pathologic change, alterations of kidneys or other structures being considered as secondary to it. Several studies on the distribution of arteriosclerosis have been made on autopsy material with varied interpretations of the significance of the findings.[2, 3, 4]

Clinical investigation has been carried out by sections of specimens from the skeletal muscles,[5] from the standpoint of correlating sclerosis of arterioles with hypertension. Study of the retinal vessels is easily carried out, and often the changes found are not only diagnostic of hypertension but may indicate definitely the type of hypertension.[6] Such changes may be found to indicate a former hypertension even though the pressure at the time of examination is found to be lowered.[7]

Pathologists have long noted, at autopsies of individuals with hypertension that gross evidence of arteriosclerosis often is marked in one organ and absent or only slight in other organs. Sclerosis of the aorta or its large branches is not necessarily associated with organ changes. The three important structures involved frequently are the kidneys, brain, and heart. In explanation of this association it was usually said that these were "vital" organs and that arteriosclerosis in any such organ was accompanied by increased blood pressure, in order to drive sufficient blood through it to maintain life.

This simple mechanistic explanation is disputed by the work of Page[8] and his co-workers, who interpret their results as indicating the formation of the specific substance "renin" by a damaged kidney, the renin then being changed by a blood activator into the effective antiotonin, which increases blood pres-

*From the Department of Pathology, Northwestern University Medical School, Chicago, Illinois.

Received for publication, October 31, 1942.

sure. As a result of his extensive and important work on hypertension, Goldblatt,[9] also, believes that the initiating principle derives from the kidneys exclusively.

Only one short note[10] has been found concerning the production of chronic hypertension by operative reduction of blood flow to the brain. Observations of the acute rise of blood pressure with sudden decrease of the cerebral blood supply[11] have long been on record. The injection of kaolin into the cisterna magna has been found to result in hypertension.[12] This is believed to be associated with a communicating type of hydrocephalus, with impaired drainage of the cerebrospinal fluid through the perineural and perivascular lymphatics, although in rats the fluid content of the brain tissue was not increased.[13]

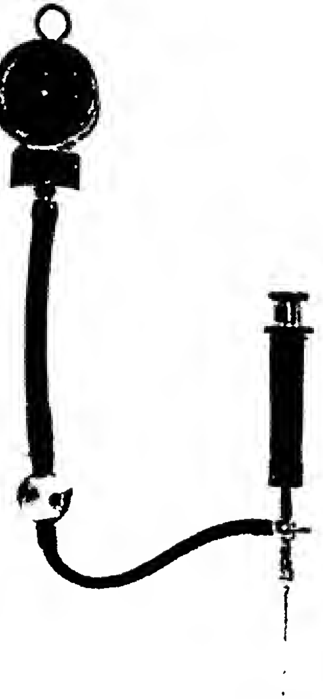

Fig. 1.

We have been interested, over a period of four years, in the effect on the blood pressure of a series of arterial ligations in dogs planned to lessen the blood supply of the brain. The ligations were done in stages, the sequence of operations being changed from time to time. The total series included the ligation of both common carotids in the region of the sixth cervical vertebra, and their dissection upward including the dissection, ligation, and excision of all branches as far out as possible from the bifurcation. Both carotid sinuses were completely removed. Also, the vertebral arteries were ligated just distal to their points of origin, and in the suboccipital region just before they enter the vertebral canal. Afterwards, various exploratory operations were performed for the ligation of any anomalous or collateral arteries which could be found.

As might be expected, the mortality in such a long series of operations was quite high, but decreased with knowledge of when and how to do the ligations. A total of 47 dogs has been used, with 10 of them successfully carried through the series.

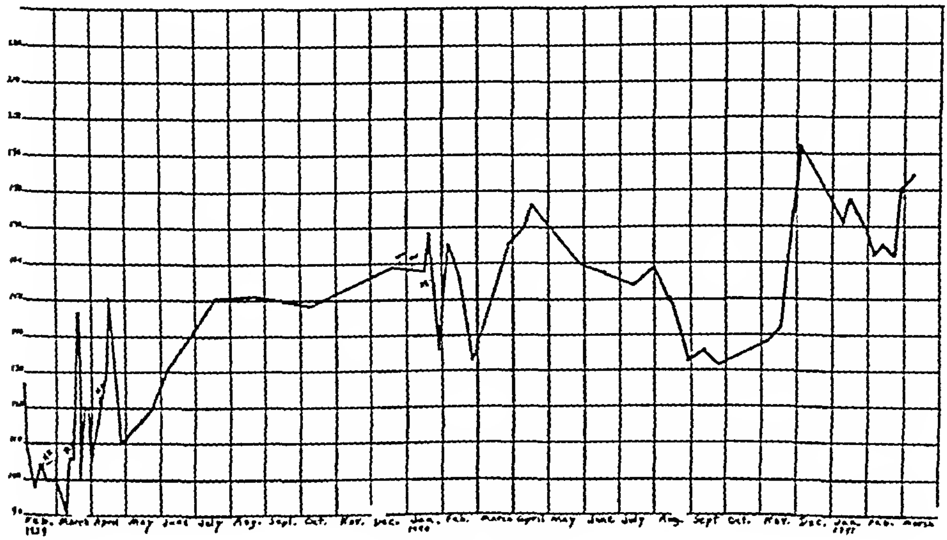

Fig. 2.—Dog 1.

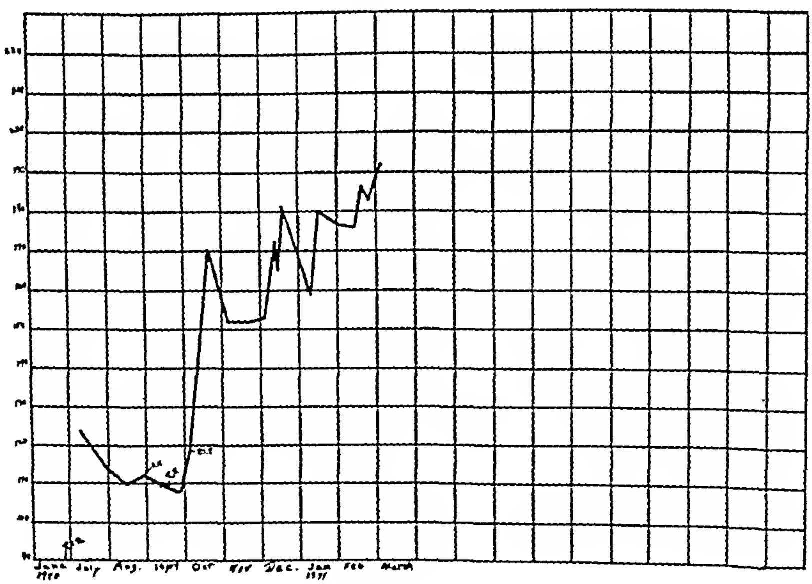

Fig. 3.—Dog 2.

Blood pressures were taken by direct puncture of the femoral artery with a twenty-gauge needle connected through a three-way valve with a glass syringe and an aneroid manometer (Fig. 1). Five per cent sodium citrate solution was drawn up into the syringe and forced out into the rubber tube, so as to fill the glass bulb about one-third full and raise the manometer pressure to about the expected blood pressure of the animal. With the stopcock

turned so as to allow blood to show in the citrate of the syringe, the needle was inserted into the femoral artery and the stopcock then turned to connect the needle with the pressure system. The manometer pointer oscillated from four to six points on the average, and the midpoint of the oscillations was taken as

Fig. 4.—Dog 4.

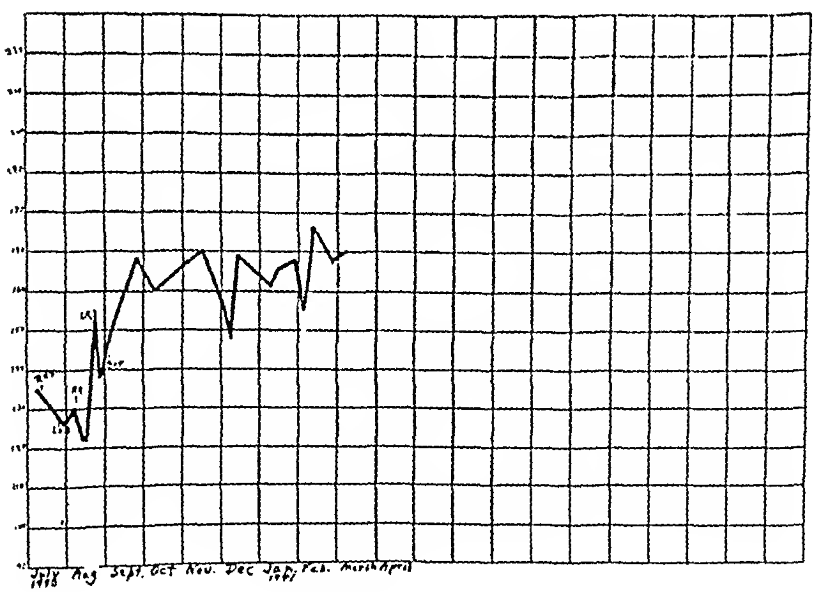

Fig. 5.—Dog 5.

the mean blood pressure. With a period of training the dogs became accustomed to the puncture and would lie quietly while it was carried out. Large dogs, usually of the police dog breed, were used.

The type of blood pressure response to the ligations, together with the time relationships, are shown in the accompanying graphs. Eight of the ten animals carried through the operative series showed a definite, and some of these a marked, rise of blood pressure. This ranged from controls of 100 to

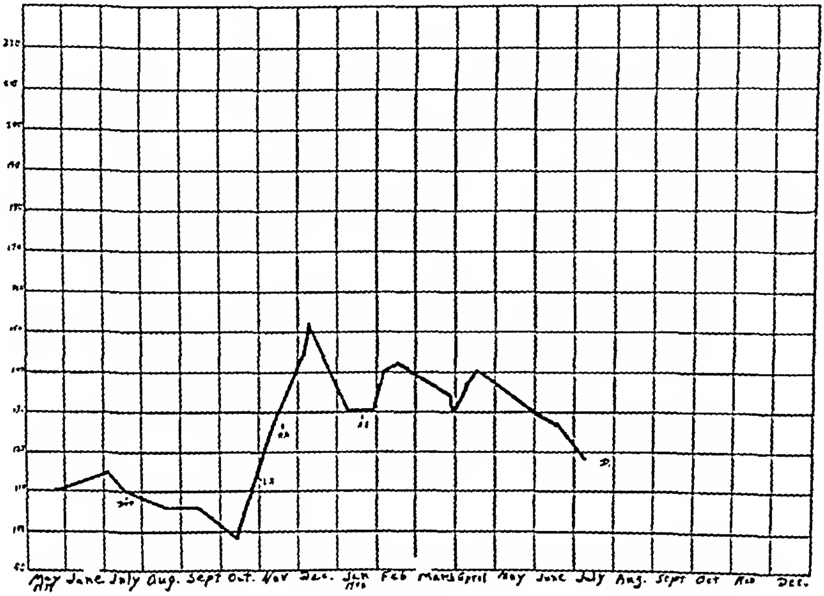

Fig. 6.—Dog 7.

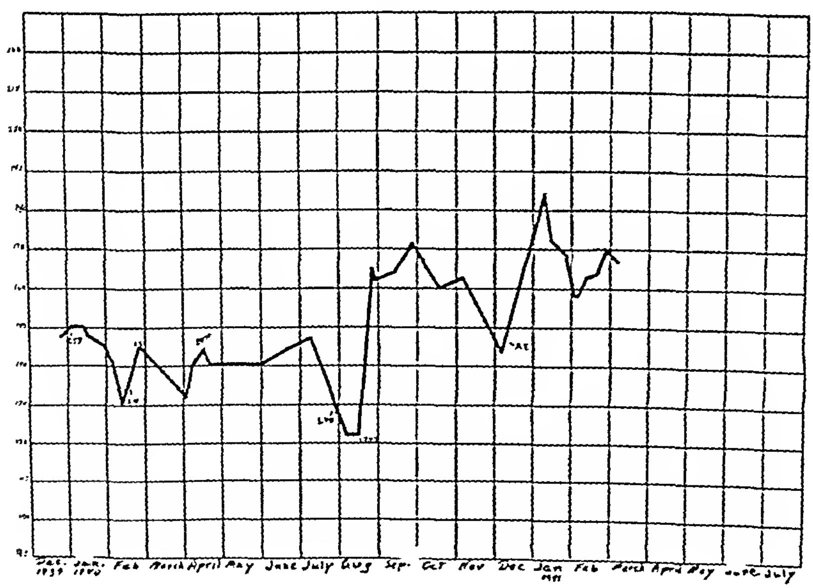

Fig. 7.—Dog 8.

120 mm. Hg usually, up to high points somewhat over 190 mm. Hg. The graphs illustrate the somewhat irregular curves, with variables up to 20 mm. Hg. Such variations occurred from day to day, often for no accountable reason. Two of the ten dogs showed no sustained rise of pressure.

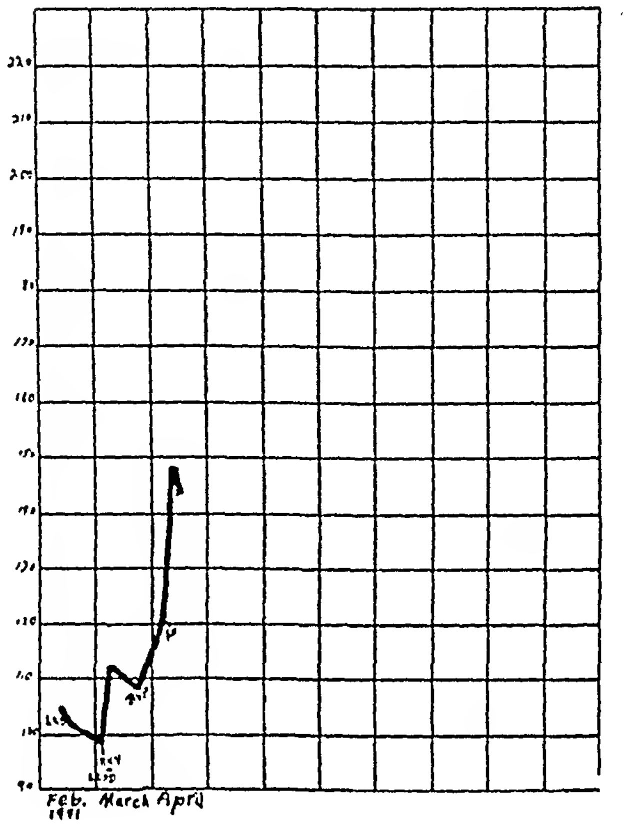

Fig. 8.—Dog 9.

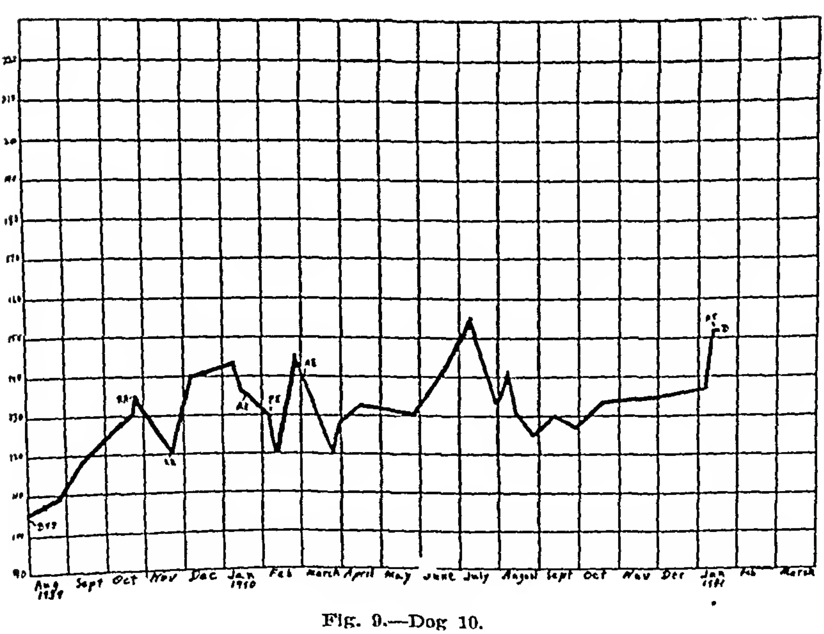

Fig. 9.—Dog 10.

Several workers have reported acute experiments with the production of hypertension by section of the aortic depressor nerves[14, 15, 16, 17] together with denervation of the carotid sinuses. Chronicity of this hypertension has been reported,[18, 19, 20] but others[21, 22] have failed to produce chronic hypertension by this means; this result is shown in our work also.

In four of our ten animals we completely removed the sinuses before the vertebral arteries were sectioned in the occipital region, so that the circulation to the brain was not diminished by their removal. In the graphs of Dogs 2 and 4 the blood pressure is shown to be uninfluenced by removal of the carotid sinuses, whereas hypertension was established later, after the vertebral arteries had been occluded in the occipital region. Experiment on Dog 8 was started by denervation of both carotid sinuses as a single operation. This was done on each side by stripping all nervous and fascial tissue from the common carotid and its branches for a distance of two or more cm. from the bifurcation in all directions. No rise of blood pressure occurred within six weeks. Over a period of five months the series of ligations was performed on this dog, which developed a heightened blood pressure a week after the last operation. Experiment on Dog 9 was begun with removal of the right carotid sinus, complete denervation of the left one, and ligation of the left cranial thyroid artery. No rise of blood pressure occurred within two weeks. Both vertebrals were then tied in the occipital region. After two more weeks both vertebrals and both common carotids were operated low in the neck, and a pronounced blood pressure increase developed.

We believe that denervation or removal of the carotid sinuses has no sustained effect on the blood pressure.[23]

The rise of blood pressure which occurs after multiple cerebral artery ligations appears to be directly associated with the interference with cerebral circulation.

In the dog, cerebral ischemia is difficult to achieve and still more difficult to maintain. Andreyev[24] has studied the development of cerebral collaterals formed after interruption of the major arterial supply to the head. By injection and x-ray he demonstrated quite strikingly the large number of collaterals promptly formed and the arteries involved in their formation. Multiple exploratory operations on our dogs revealed that newly formed arteries developed with a falling blood pressure curve. We are led to believe that once a high blood pressure has been developed by our method, a sustained drop of pressure in an otherwise healthy dog indicates the formation of collateral channels supplying an adequate amount of blood to the brain.

The mechanism by which hypertension is produced by arterial-ligation ischemia of the brain is not known. Either a nervous mechanism or a humoral one may be active. Anrep and Starling[25] demonstrated that a nervous mechanism can initiate hypertension in acute cerebral ischemia. This hypertension was prevented by section of the cord between the vasomotor centers and the sympathetic outflow. The humoral factor had been ruled out.

Page and his co-workers have brought forward evidence to indicate that constriction of the renal artery causes the kidney to produce a humoral mediator of hypertension.[6] Similarly, the hypertension produced by cerebral artery ligation may result from a hypertensive substance formed in the ischemic

brain. To date no work bearing on the presence or identity of such a substance has been performed.

SUMMARY

Chronic hypertension has been produced in dogs by ligation, in series, of the arteries supplying the head.

Removal or manipulation in situ of the carotid sinuses alone has no prolonged effect on the blood pressure of dogs.

THE HUMAN SKIN AS A CONDUCTOR OF 60-CYCLE ALTERNATING CURRENT OF HIGH INTENSITY, STUDIED ON "ELECTROSHOCK" PATIENTS*

HANS LÖWENBACH, M.D., AND JASPER E. MORGAN, PH.D., DURHAM, N. C.

THE human skin as a conductor of alternating currents has been the subject of many studies,[1] and it was soon shown that it does not act like any ordinary conductor, either metallic or electrolytic. These studies, however, were limited to currents of ten to fifteen milliamperes or less, partly because of the pain produced and partly from fear of causing lasting damage. While currents of higher intensity have been used on the skin of corpses, these experiments were unsatisfactory because of the probability that living and dead skins behave differently. Some information has come from industrial and domestic accidents, but it is far from precise and is frequently vitiated by erroneous computations.[2]

A method has been recently developed of treating mental patients with strong electric shocks applied directly to the head, so as to produce a minor or major convulsion.[3] This has provided an opportunity for extending these experiments and making more precise measurements.

METHODS

The apparatus used for treatment is very simple, consisting of a mechanical relay to make and break the circuit, the timing of which is controlled by a condenser.[4] Round copper plates, 5 cm., serve as electrodes and are attached to the head with even pressure, after a small amount of electrode jelly (sodium chloride, glycerine, tragacanth, and water) has been rubbed into the skin. In some experiments the jelly was omitted. In the first series of experiments the skin resistance of 31 patients was observed during 98 single treatments. Before the "shock" current was passed, a potential difference of about 20 microvolts was applied through the electrodes, and the resulting current was recorded with an ink-writing oscillograph. The impedance, that is, the potential difference divided by the current, was easily determined from a calibration chart.

The impedance-testing circuit was then disconnected, and a voltage varying from 50 to 120 volts was applied through the same electrodes for intervals of 1/10 to 4/10 of a second. The "shock" current was recorded by another ink-writing oscillograph during the time of current flow. The ink-writing oscillographs were adapted from the Grass electroencephalograph by using only the final power amplifier for each section.

After the relay had broken the current, twenty microvolts were again applied to the electrodes as quickly as a hand-operated switch would allow. The impedance was then recorded for various times, sometimes extending over 15 minutes. In a second series of experiments, the "shock" current was recorded by a Matthews oscillograph capable of following frequencies up to 15,000 cycles. This was done in order to see whether the form of the current at any time deviates from the sine form.

---

*From the Department of Neuropsychiatry and the Department of Physiology, Duke University School of Medicine, Durham, N. C.
Received for publication, October 24, 1942.

RESULTS

In agreement with previous workers who made observations with ballistic instruments,[5] we find that the current resulting from the application of voltages between 50 and 120 is much higher than expected from the impedance originally found. Almost immediately after the current is made, the impedance falls and remains at a low level during the entire time of current flow.

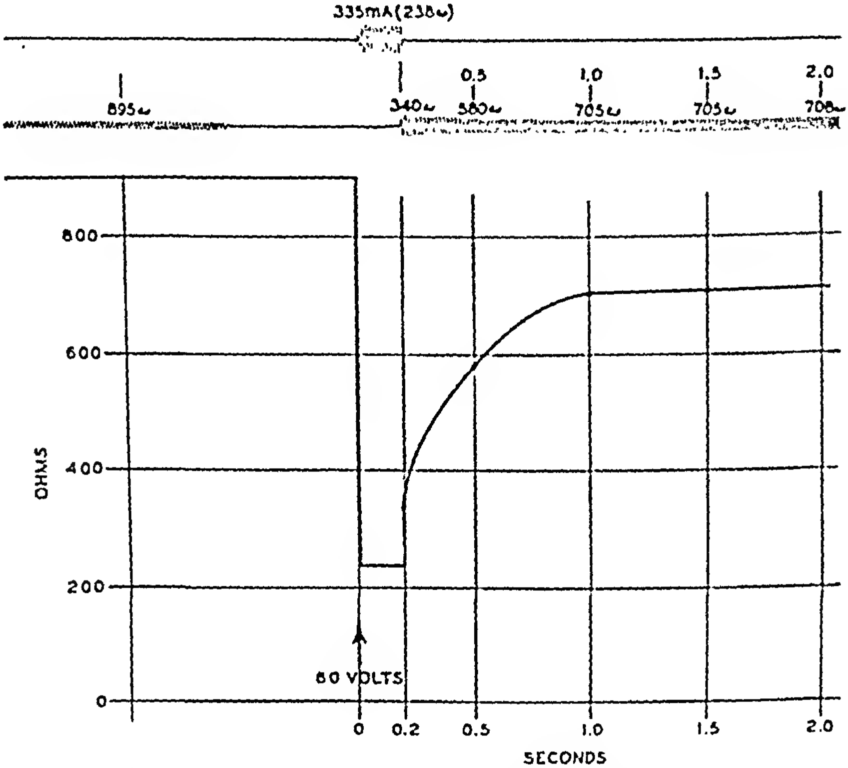

Fig. 1.—Skin resistance to 80 volts A.C. *Upper part:* Original tracings of skin resistance to 20 microvolts before and after "shock" and tracing of current during "shock." *Lower part:* resistance curve as derived from these tracings.

If the initial impedance is 2,000 ohms or less, it drops to a value between 300 and 120 ohms (Fig. 1). The exact value depends on how many volts are given, the lower values occurring after higher voltages. When the current is broken, the impedance rises again. Frequently there is an initial sudden rise of the impedance of 80 to 150 ohms, but in other cases the rise takes place gradually. It then increases slowly over a period of many seconds, and finally approaches the original value asymptotically. After lower tensions the pre-"shock" impedance returns within a shorter interval of time than after higher ones. A second shock, given before the impedance has reached the original value, produces the same current as the previous one; that is, no further drop of the impedance occurs. If all other components are the same, the drop occurs almost instantaneously, and during the next 2 to 3 cycles only a slight further decrease takes place (Fig. 2*b*). If, however, the resistance is higher than 2,000 ohms to begin with, as for example when no electrode jelly is being used, the

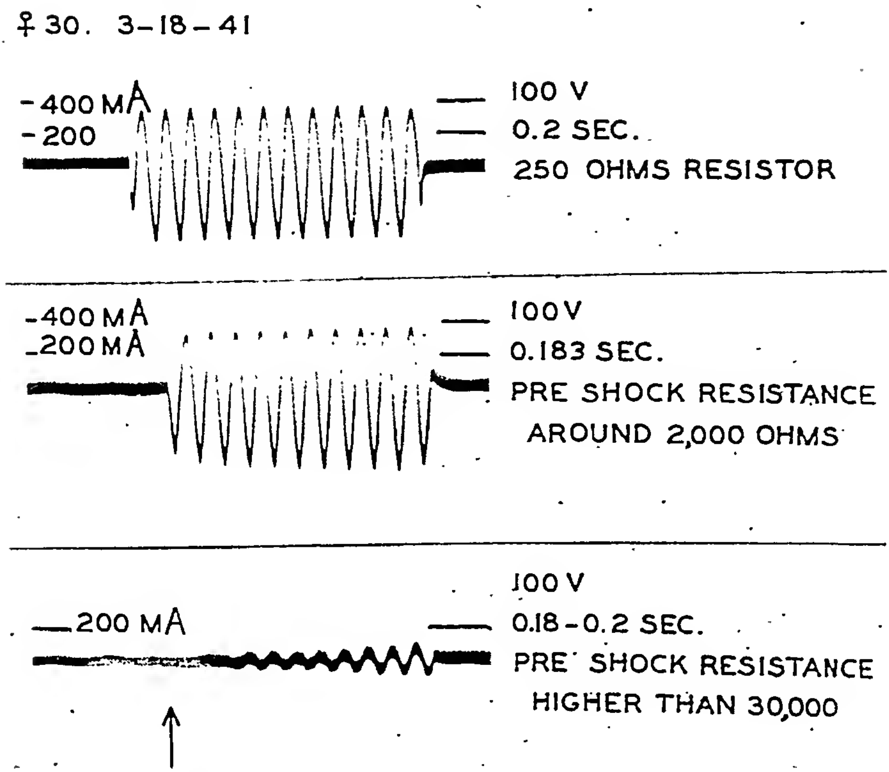

Fig. 2.—Oscillograms (Matthews' oscillograph) of 100 volts A.C. (*a*) passing through 250 ohm wire-wound resistance; (*b*, *c*) passing through human skin.

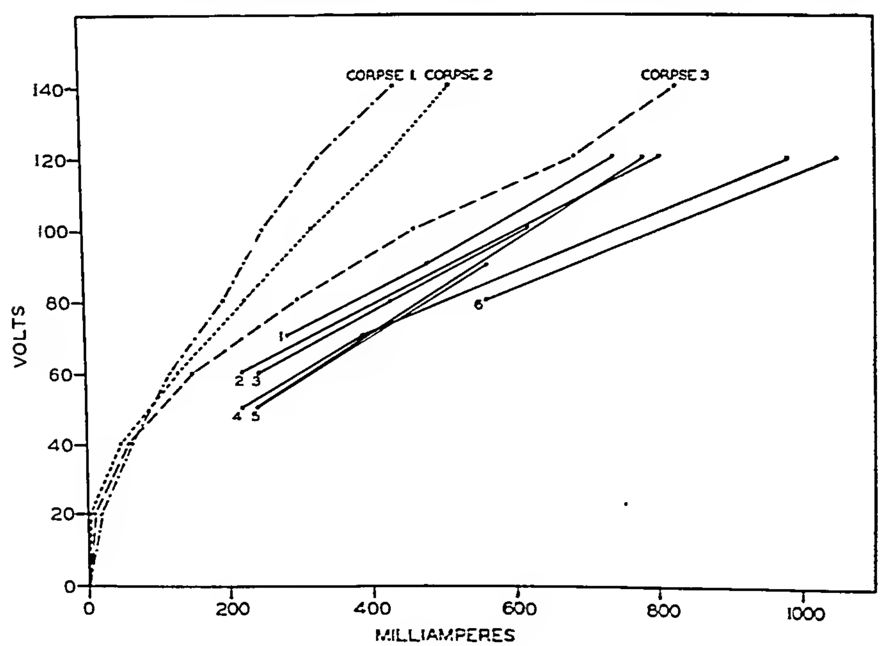

Fig. 3.—Voltage/current for 6 patients and for 3 corpses. Corpse 1 had been dead for 90 hours; corpse 2, for 24 hours; corpse 3, for 3 hours. The drop of the skin resistance when higher tensions are applied is larger in the living skin than in the dying skin. The voltage/current curve of the latter tends to approach a straight line.

current increases very gradually, and assuming the same time of current flow, it may never reach the same high level as otherwise (Fig. 2c).

No deviation from the sine form was observed in these experiments, and a few recordings with a cathode ray oscillograph point in the same direction.

The living skin then behaves like an electrolytic condenser which breaks down when tensions above 50 volts are applied. The impedance of the uninjured dying skin of the corpse is of the same order of magnitude as that of living skin for tensions up to 50 volts. If higher tensions are applied, the impedance of dying skin does not drop to such low values as are observed under living conditions. The longer the time after death, the less the drop, until finally the voltage/current curve approaches a straight line (Fig. 3).

Thus, it seems obvious that the sometimes elaborate attempts to measure the resistance of the skin before an electric shock treatment are not necessary. With electrode jelly and the electrodes in good contact, the resistance will usually be below 2,000 ohms and, during the time of current flow, will be between 150 and 250 ohms.

SUMMARY

The reactions of the living human skin as a conductor of 60-cycle alternating current up to 1,000 milliamperes was studied on 31 mentally ill individuals in 98 experiments. When 50-120 volts are given for 0.1-0.4 sec., the impedance drops instantaneously to a value between 270 and 120 ohms regardless of the original impedance, provided this is kept at or below 2,000 ohms. Under these circumstances there is no further change of the impedance during the time of current flow. When the current is broken, the impedance—to 20 microvolts—rises suddenly 80-150 ohms, depending on the "shock" tension applied; it then increases over a period of many seconds, approaching the original value asymptotically. The skin of human corpses reacts similarly to that of living individuals, but the impedance drop is less the longer the interval between the time of death and of examination.

SOME NEW ASPECTS OF MORPHINE ACTION: INFLUENCE OF PROSTIGMINE METHYLSULFATE ON EXCRETION*

DONALD SLAUGHTER, M.D., C. R. TREADWELL, PH.D., AND J. WESLEY GALES, M.D.
DALLAS, TEXAS

IT IS now well known (Gross and Thompson[1]) that the greater part of an injected dose of morphine sulfate can be recovered from the urine and feces of accustomed and nonaccustomed dogs. These authors pointed out, however, that a large part of excreted morphine was bound or conjugated and had to be hydrolyzed before it could be recovered.

Further, there is evidence[2] which indicates that prostigmine methylsulfate alters the accustoming† (tolerance-inducing) properties of morphine in dogs.

Recent work[3] suggests that prostigmine methylsulfate enhances the analgetic effects of morphine in cats. If this is true, the reason for the enhancement may lie in the action of prostigmine methylsulfate on the conjugation, destruction, and excretion of morphine.

For these reasons it seemed advisable to determine if the excretion of morphine was influenced by prostigmine methylsulfate. We were particularly interested in ascertaining whether prostigmine methylsulfate altered morphine excretion during withdrawal of morphine, comparatively, in accustomed and nonaccustomed animals and to note if the amounts of free or combined morphine were materially changed. In order to test such a hypothesis, both accustomed and nonaccustomed animals were used.

TECHNIQUE

The animals used in this study were all healthy female dogs. They varied in weight from 8 to 17.7 kg., but animals of similar weights were paired so that the difference in a pair (one accustomed and one nonaccustomed animal) was never greater than 2 kg. Five accustomed and five nonaccustomed animals were studied. A routine as outlined by Pierce and Plant[4] was followed in maintaining the dogs on a constant water and caloric intake. During a 6- to 7-day control period and during a 6 day excretion period, the normal body weights of these animals were not materially altered. The accustomed animals had previously been receiving 20 mg./kg. of morphine sulfate daily for 10 months or longer.

As mentioned above, one point of interest in this study was to compare the level of morphine excretion during withdrawal in accustomed and nonaccustomed

*From the Laboratories of Physiology and Pharmacology, and Biochemistry, Baylor University College of Medicine, Dallas, Texas.

A preliminary report was read at the Federated Society Meetings held in Chicago on April 15-19, 1941.

This work was aided by a grant to one of us (DS) from Hoffmann-La Roche, Inc., Nutley, New Jersey.

Received for publication, November 3, 1942.

†We prefer the term "accustomed" to the usual term "addicted," because in our opinion it reflects better the meaning of the French word "accoutumance."

dogs and to note what influence, if any, prostigmine methylsulfate had on the amount and form of morphine excreted. In order to adequately accomplish this, the following procedure was used: each animal, whether accustomed or nonaccustomed, received subcutaneous doses of 20 mg./kg. of morphine sulfate daily for an arbitrary three-day period. Then each animal was withdrawn for three days following the last dose. The morphine excretion over this period of six days constituted the control values. With these values were compared the amounts of morphine excreted after the same subcutaneous dose of morphine and over the same period but with the addition of prostigmine methylsulfate in subcutaneous doses of 0.2 mg./kg. administered in conjunction with the morphine as well as during the withdrawal period. The 24-hour output of feces was collected once daily. The animals were catheterized twice daily, and the urines were pooled, comprising the 24-hour output. The 24-hour sample of urine was analyzed individually for free and combined morphine, and the 24-hour sample of feces was analyzed for total morphine.

The extraction of free and of combined morphine after hydrolysis in the urine and the analysis of total fecal morphine was carried out as described by Gross and Thompson.[1] The morphine was determined colorimetrically by the diazotization procedure originally outlined by Pierce and Plant.[4] Known amounts of morphine were added to urine and feces. We were easily able to detect such known amounts and thus establish the validity of the method employed. Control diazotization experiments showed that prostigmine methylsulfate did not in any way alter the determination of morphine by this method.

RESULTS

Table I summarizes the effects of prostigmine methylsulfate on morphine excretion in accustomed and nonaccustomed animals. It is obvious that the total per cent of injected morphine excreted in urine and feces is reduced when prostigmine methylsulfate is administered with the morphine sulfate. This total difference is about the same in both groups of animals although there is a tendency for a greater disparity in the accustomed dogs. If the lessened excretion of morphine is broken down into component parts, the decreased urinary excretion in the nonaccustomed dogs is reflected almost two to one in the combined, as compared with the free form as shown in the following analysis.

ANALYSIS OF TABLE I. URINARY MORPHINE OUTPUT

Under prostigmine methylsulfate the total percentage reduction in the urinary morphine excretion in nonaccustomed dogs (NA) was 17.6 per cent; in accustomed dogs (A), 17.2 per cent; i.e., $\frac{67.2 - 55.4}{67.2} \times 100 = 17.6$ per cent and $\frac{69.1 - 57.2}{69.1} \times 100 = 17.2$ per cent.

From Table I we see that the actual percentage reduction of urinary morphine output under prostigmine is: For NA dogs, *free* 4.2 per cent; *comb.* 7.6 per cent; for A dogs, *free* 5.0 per cent; *comb.* 7.0 per cent. (Since fecal excretion represents only a small percentage of total excreted morphine, it is not considered in this analysis.)

The difference between the reduction in free and the reduction in combined morphine outputs was greater in NA dogs than in A dogs. Expressed as per cent of the reduction in free form for NA dogs, this difference was 81 per cent of the reduction of free form, while for A dogs it was 40 per cent of the reduction in free form; i.e., $\frac{7.6 - 4.2}{4.2} \times 100 = 81$ per cent, etc.

The percentage reduction of excreted morphine after prostigmine methylsulfate was for *Free Morphine* in NA dogs, 28 per cent; in A dogs, 34 per cent; for *Combined Morphine* in NA dogs, 14.6 per cent; in A dogs, 12.8 per cent; i.e., $\frac{15.0 - 10.8}{15.0} \times 100 = 28$ per cent, etc.

TABLE I

EFFECT OF PROSTIGMINE METHYLSULFATE ON MORPHINE EXCRETION IN NONACCUSTOMED (NA) AND ACCUSTOMED (A) DOGS

(Values Represent Average Per Cent Recovery of Total Dose of Morphine Administered)
(All Animals Received 20 Mg./Kg./Day of Morphine for 3 Days)

NUMBER OF ANIMALS		PROSTIGMINE METHYLSULFATE MG./KG./DAY		TOTAL URINE + FECES %		URINE						FECES %	
						TOTAL %		FREE %		COMBINED %			
NA	A	NA	A	NA	A	NA	A	NA	A	NA	A	NA	A
5	5	0.0	0.0	71.8	75.8	67.2	69.1	15.0	14.7	52.2	54.5	4.6	6.6
5	5	0.2	0.2	61.1	62.4	55.4	57.2	10.8	9.7	44.6	47.5	5.6	5.2

TABLE IA

OUTPUT OF FREE AND COMBINED MORPHINE IN TERMS OF TOTAL URINARY OUTPUT AS 100 PER CENT

"PROSTIGMINE"	TOTAL %		FREE %		COMBINED %	
	NA	A	NA	A	NA	A
0.0	100	100	21.3	21.2	77.7	78.8
0.2	100	100	19.5	17.0	80.5	83.0

The percentage reduction in amount of excreted, free morphine is slightly greater in A dogs than in NA dogs but is probably not significant. The percentage reduction in amount of excreted, *combined* morphine is slightly less in A dogs than in NA dogs, but the difference is also probably not significant.

If the figures are expressed as fractions of total urinary morphine found, instead of fractions of the administered morphine, the urinary figures of Table I are as follows: (See Table IA.)

Relative changes: Free morphine output reduction by prostigmine methylsulfate in NA vs. A dogs: NA dogs, 8.5 per cent; A dogs, 19.8 per cent. Hence on a basis proportional to the total morphine found, relative reduction of free morphine output by prostigmine methylsulfate is 2 to 3 times as great in A dogs as in NA dogs after prostigmine methylsulfate. There appears to be a relative *increase* of output of *combined morphine* after prostigmine methylsulfate: in NA dogs, 3.6 per cent; in A dogs, 5.3 per cent.

By way of explanation, the thought arises that perhaps prostigmine methylsulfate has less action on the excretory mechanism than it has on an earlier stage of morphine action and metabolism. That is, that the proportion of free

and combined morphine is an independent factor as far as prostigmine methylsulfate is concerned, and that any variation is more a function of the total amount excreted rather than total dose administered. When total excreted morphine of either accustomed or nonaccustomed animals is considered, we see that after prostigmine methylsulfate, 17 per cent less is excreted.

DISCUSSION

These results clearly indicate that prostigmine methylsulfate decreases the excretion of morphine in accustomed and nonaccustomed dogs. It seems fair to assume that such an effect demonstrates the ability of prostigmine methylsulfate to alter the potential effectiveness of morphine in the animal body. We have long felt that prostigmine methylsulfate prevented the development of tolerance in animals,[2] and clinical observations[7] using combinations of morphine and prostigmine methylsulfate suggest a similar effect.

The greatest actual decrease in excretion of morphine following prostigmine methylsulfate administration is reflected in the combined form. There is also, however, a reduction of output of the free form. In either case it seems possible to suggest that prostigmine methylsulfate alters the effectiveness of morphine in the body, either by causing retention of both forms or by increasing the rate of destruction of both forms in the body so that less can appear in the urine. In proportion to that amount of each form excreted without prostigmine methylsulfate, the greater proportional decrease of output is in the free morphine output; this is also evident in the relative shift in proportion of free and combined urinary morphine shown in Table IA.

Gross[6] has suggested that the combined form of morphine may be responsible for hypnosis and analgesia. If this is true and if retention of both forms of morphine in the body is the mechanism of prostigmine methylsulfate reduction of urinary output of morphine, one might thus explain, at least in part, the potentiation of morphine hypnosis and analgesia by prostigmine methylsulfate. The retention of free morphine might lead to a greater formation of combined morphine, which would still further potentiate the hypnotic action under Gross's hypothesis. Retention would result in a higher concentration of the effective form reaching the loci of action, and thus would simulate the effects of higher doses of morphine.

SUMMARY

1. Prostigmine methylsulfate in suitable doses decreases the total urinary excretion of morphine in accustomed and nonaccustomed dogs.

2. The bulk of the decreased morphine excretion is reflected in the combined form.

3. There is a relative shift in proportions of free and combined morphine in the urine, in the direction of a higher proportion of the combined form. This shift is greater in nonaccustomed dogs than in accustomed dogs.

4. In the light of a retention of morphine in the body produced by prostigmine methylsulfate, the mechanism of potentiation of morphine hypnosis and analgesia by prostigmine methylsulfate is discussed.

IMMUNOLOGIC AND TOXIC PROPERTIES OF CASEIN DIGEST AS PREPARED FOR PARENTERAL ADMINISTRATION*

HOWARD C. HOPPS, M.D., AND JAMES A. CAMPBELL, B.S., CHICAGO, ILL.

ALTHOUGH hypovitaminosis continues to receive preponderant emphasis in studies on malnutrition, the effects of protein deficiency are not to be minimized. In addition to such obvious effects as inanition, failure of growth, anemia and nutritional edema, protein deficiency (hypoproteinemia) affects both quantitatively and qualitatively the regeneration of tissue; it predisposes the liver to injury by toxins, and it seriously interferes with the synthesis of antibody globulin. Hypoproteinemia is an important cause of delayed wound healing and wound dehiscence.[1] An increased susceptibility of the liver to injury by such toxic substances as chloroform and arsphenamine during a state of protein depletion has been shown, and the fact that feeding of protein exerts a marked protective action against injury has been demonstrated.[2] The effect of protein depletion on resistance to infectious disease was the subject of discussion in the presidential address to the American Association of Immunologists this year.[3] Evidence was presented to show that hypoproteinemia in animals markedly decreased their ability to synthesize antibody globulin, thus interfering with one of their most important defense mechanisms against infectious disease —the ability to develop active immunity.

The treatment or prevention of the protein deficient state is often difficult. Administration of protein by mouth may be impossible, or digestive disturbances may prevent assimilation of fed protein. Associated with these conditions there is often a marked increase in protein requirements either from abnormal loss of protein or from increased metabolism. Parenteral therapy to relieve a condition of protein deficiency would be of especial importance in preparation of patients for surgery as well as in helping to maintain their nutritional state during the early postoperative period. In a discussion of hypoproteinemia and its relation to surgical problems, Ravdin[4] states, "No consideration of fluid and electrolyte loss and their restitution is sufficient unless the plasma protein is simultaneously considered."

*From the Department of Pathology, University of Chicago, Chicago.

Received for publication, November 4, 1942.

For these reasons a source of protein which may be safely administered parenterally is much to be desired, to supplement or complement solutions of carbohydrates, salts, and vitamins.

Over thirty years ago experiments were first done to develop such a source of protein. Success has come only recently, however. The gradual accumulation of facts leading to the demonstration that protein requirements could be completely or almost completely met by supplying ten "essential" amino acids was probably the most influential factor in this respect. In a Harvey lecture in 1934[5] Rose said, "Indeed it is not wholly improbable that methods may be developed whereby this ideal mixture (amino acids) may be employed for parenteral administration to human subjects when the prevention of undue loss of body structure is an important consideration."

This "ideal mixture" of amino acids has been closely approached in recent years although it comes not from a synthetic mixture of purified amino acids as Rose had postulated, but from the hydrolysis of a complete protein. Rapidly accumulating experimental data[6, 7, 8, 11, 13] indicate that such preparations are utilized for protein synthesis and that when given parenterally, as a sole source of nitrogen, they serve to maintain nitrogen equilibrium and support normal growth and tissue repair.

A commercial preparation of casein hydrolysate designed to serve as a parenteral source of protein food has been available for experimental use and has received much study during the past five years.* Experience with new drugs (e.g. amidopyrine, dinitrophenol, sulfanilamide, etc.), has indicated, however, that although initial experimental trials reveal no significant toxic action, there may be decided deleterious effects when such drugs are subject to widespread or general use. For this reason, new drugs should always be subjected to thorough experimental study expressly designed to detect or to determine the nature of possible toxic effects. The demonstration of such toxic or deleterious action of specific drugs need not result in absolute contradiction to their use; yet the knowledge of such untoward effects may allow for intelligent, directed caution or for the application of corrective measures. With these thoughts in mind experiments were undertaken to determine whether or not amino acid solutions prepared from hydrolyzed casein were toxic.

In preparations made from proteins and intended for intravenous administration to human beings the possibility of allergic reaction must always be considered. Since casein is an antigenic protein, there is the possibility that a product derived from casein might retain some of these antigenic properties. The first consideration, therefore, is to determine whether or not casein hydrolysate is antigenic. Since it is generally accepted that complete hydrolysis destroys the biologic speciation of native proteins, demonstration of nonantigenicity in these products would be strong evidence that complete hydrolysis had been accomplished.

Two commercial preparations of casein hydrolysate were selected for testing. These will be referred to as products A and B. Concerning product A, its manufacturer states that efforts have been made to sensitize guinea pigs with A and to shock milk-sensitive pigs with A solution and that all such studies have been negative, indicating the absence of antigenic properties; however, no

*Amigen, an enzymatic hydrolysate of casein, prepared by Mead Johnson & Co.

details of these experiments are available in the literature, nor are there experiments specifically directed toward the detection of pork protein which might have been introduced during the course of hydrolysis, a process accomplished by the action of ground pork pancreas. Concerning the antigenic properties of product B, an acid hydrolysate of casein, its manufacturer states that "biologic speciation in most instances is due to the prosthetic groups attached to the protein. Most proteins shown to be antigenic substances are despeciated by enzymatic hydrolysis." The product in question, however, is not an enzymatic hydrolysate. The works of Hill and of Altshuler are cited to substantiate further claims that this particular casein digest is nonantigenic. Neither Hill nor Altshuler used the particular preparation under consideration. Hill[7] maintained infants allergic to milk on casein digest for periods up to three months. In about half of the cases eczema was relieved. Altshuler, Hensel, and Sahyun[8] injected two rabbits with an acid hydrolysate of casein and were subsequently unable to produce anaphylactic shock in these animals. These findings are inconclusive, however, because of the unsuitability of rabbits for anaphylactic tests.

EXPERIMENTAL

ANTIGENIC PROPERTIES OF CASEIN HYDROLYSATES

The first series of experiments consists of determining whether or not preformed antibodies to casein react with hydrolysates of casein and whether or not hydrolysates of casein are in themselves capable of stimulating the formation of antibodies for themselves or for casein. Three groups of normal adult rabbits were given repeated injections of preparation A,* preparation B, and purified casein (Casein-Harris). Multiple doses of these substances were administered by intramuscular, intraperitoneal, subcutaneous, and intravenous routes. In addition, ten intramuscular "depots" of the test substance adsorbed upon alumina gel after the method of Hektoen and Welker[9] were produced. After 65 days serum precipitin titers were determined in all groups by the collodion particle method of Cannon and Marshall,[10] as well as by the usual antigen-dilution method. Precipitins for casein digest were not found in any case; neither did the animals treated with casein digest exhibit antibodies for casein. Skin tests were performed using cows' milk, 10 per cent A, and 10 per cent B. Casein-sensitized animals gave positive reactions only to milk. Animals treated with casein digests gave no positive reactions to casein nor to the casein digest with which they had been treated. These animals were bled, and the pooled serums of each group were injected intraperitoneally into corresponding groups of normal 180- to 200-gram guinea pigs. Two days later anaphylactic tests were performed. Two c.c. portions of the test substances were given via the jugular vein to the unanesthetized pigs. Casein-sensitized animals were divided into three groups. To group one, casein was given and these animals died of typical anaphylactic shock. Group two received A (10 per cent solution) with no reaction. After several hours these same animals were again injected, this time with casein, with resultant death from typical anaphylactic shock. Group three was treated in essentially the same manner as group two, except that solution B was substituted for A. Identical results were obtained.

*Kindly furnished by Mead Johnson & Co.

Twenty-eight virgin female guinea pigs weighing 150 to 180 grams were "passively sensitized" with pooled serums from rabbits treated with casein, A, or B. These animals were sacrificed at three to four days, and muscle strips (uterine horn) preparations were studied for passive sensitization using the Schultz-Dale technique. Fig. 1 shows the typical reaction of a normal uterine muscle strip to A, to B, and to casein. These test solutions (aqueous) had been adjusted to a pH of 6.8 to 7.0 by the careful addition of 0.1 N NaOH. In Fig. 2, however, the pH of test solutions A and B was unaltered (approximately 4.5). These differences in reaction to A (compare Figs. 1 and 2) are apparently the result of some change in state that occurs with neutralization of solution A, a change that is marked by the gradual formation of a rather abundant cloudy precipitate.

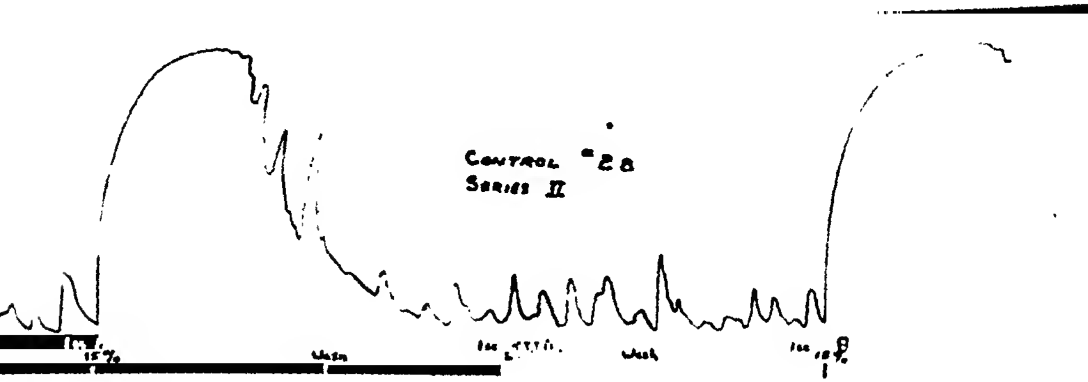

Fig. 1.

Fig. 2.

The reaction of normal smooth muscle to these hydrolysates of casein indicates the presence of some histamine-like substances, peptones, or tyramine, which may explain the frequently observed reactions of flushing, sensation of warmth, and nausea observed in patients who are administered casein digest by vein.[11, 13]

Typical reactions of the casein-sensitized group are shown in Fig. 3. An anaphylactic response has occurred to casein. The reactions of this group to solutions A and B are essentially similar to those exhibited by the control animals.

Fig. 4*A* shows a typical reaction of the A-"sensitized" group to casein and to A; these are normal reactions. Fig. 4*B* illustrates the reaction of a B-"sensitized" animal to casein and to B. This reaction to B is the most marked of any exhibited by this group; it is not a typical anaphylactic reaction, however, and the reaction to casein is as in the normal. Other animals of this group gave an essentially "normal" reaction to B.

These studies adequately demonstrate that the two preparations of hydrolyzed casein tested are incapable of stimulating antibody production, nor do they react to preformed casein antibodies.

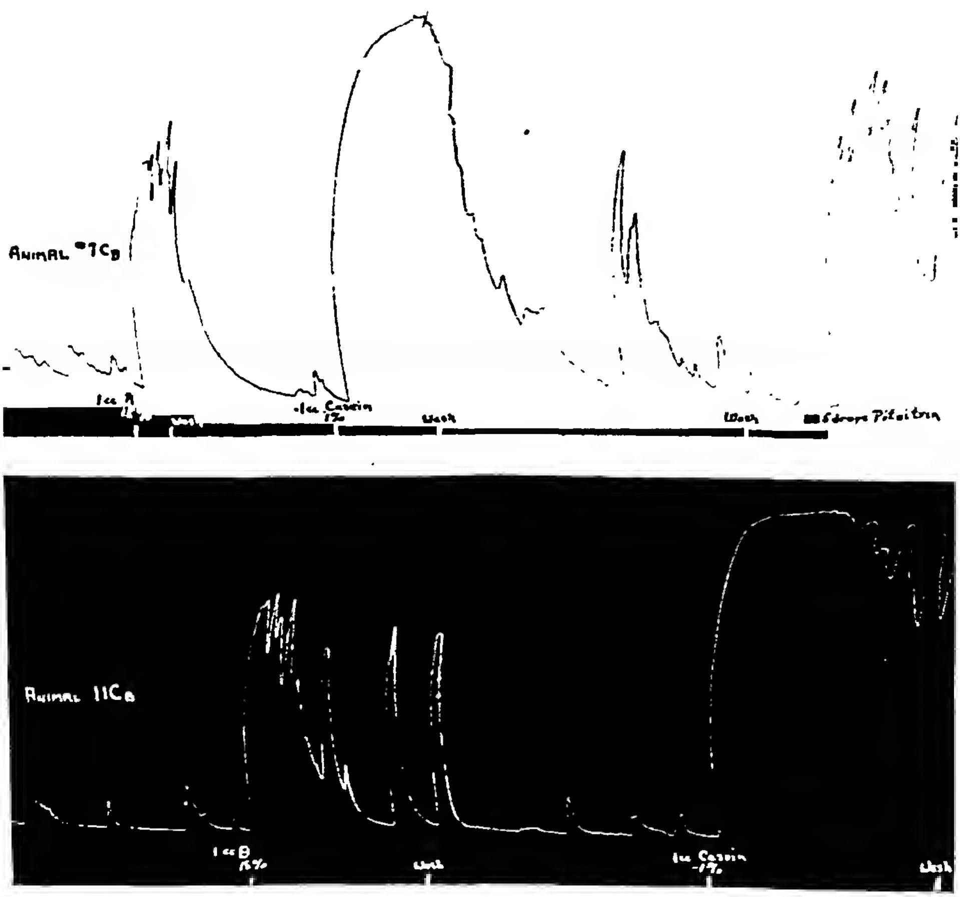

Fig. 3.

A second series of experiments concerns only product A in the preparation of which hydrolysis is accomplished by means of ground pork pancreas. The nonantigenicity of substance A has just been demonstrated, but there remains for investigation the possibility that modified pork protein exists as a partial antigen or haptene, incapable of stimulating antibody formation, but capable of reacting with preformed pork antibodies. To explore this possibility, rabbits were sensitized to swine pancreas and swine serum, as demonstrated by the presence of specific precipitins and by positive Arthus reactions. Animals treated with A failed to show precipitins or positive skin reactions to swine

serum or swine pancreas. Likewise, animals sensitized with swine pancreas or swine serum failed to show precipitins or positive skin tests against A. Anaphylactic tests were performed with passively sensitized guinea pigs in the same manner as previously described. There was no demonstrable antigenic relationship between pork proteins and product A.

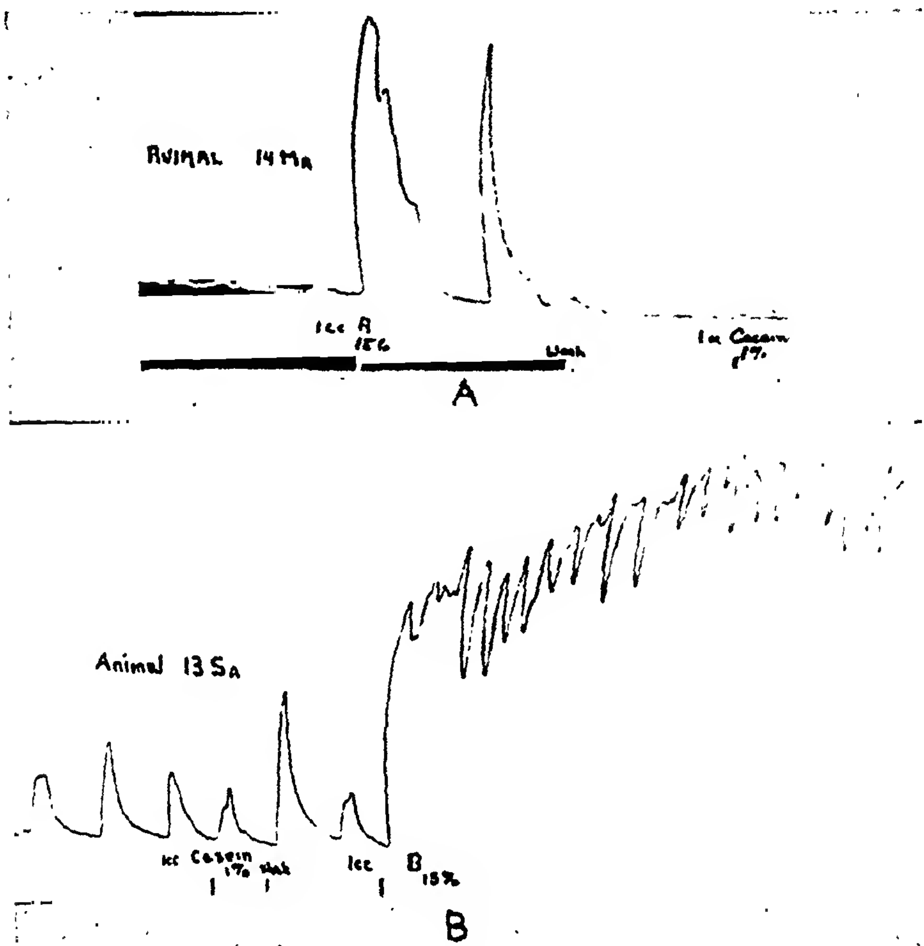

Fig. 4.

TOXIC PROPERTIES OF CASEIN HYDROLYSATES

Table I shows the hydrogen ion activity and hydrogen ion concentration of the two preparations tested. It can be seen that these solutions have a hydrogen ion concentration comparable to 1/16 to 1/12 N HCl. Their effect on the pH and CO_2 combining power of human plasma in vitro is also shown. The proportions of hydrolysate and plasma in these mixtures is comparable to that which would be attained in a 65 kg. patient given intravenously, at a single dose, 1500 c.c. of a 10 per cent solution of amino acid mixture. This is admittedly an artificial comparison in that amino acid mixture introduced into a patient would not all remain in the blood stream for the period required to administer this large quantity. From these observations it was thought that

casein hydrolysates might have a marked tendency to produce acidosis, especially in those patients who were seriously ill and who received repeated large doses of the substance. Experiments were done to evaluate this effect. Blood plasma was obtained from two patients* just before the intravenous administration of 1500 c.c. of 10 per cent amino acids (product A). This material was given over a period of eight hours and was accompanied by 1500 c.c. of 10 per cent dextrose in saline and 1500 c.c. of 10 per cent dextrose in water. Immediately upon completion of this infusion a second specimen of plasma was obtained from each patient. In patient No. 1, the CO_2 combining power dropped from 59.2 vol. per cent in the first sample to 50.5 in the second sample. In patient No. 2, the decrease was from 58.7 vol. per cent to 52.6 vol. per cent. These changes may well represent only the dilution of blood plasma resulting from administration of a large amount of hypertonic fluid. Plasma pH did not vary significantly. Similar observations were made on a third patient† to

TABLE I

HYDROGEN ION ACTIVITY AND CONCENTRATION OF CASEIN HYDROLYSATES AND THEIR EFFECT ON HUMAN PLASMA

SOLUTION	pH	0.1 N.Na OH ADDED TO BRING pH TO: (10 C.C. SAMPLE) 7.2—7.4	8.1—8.2
10% A	4.6	5.59 c.c.	12.82 c.c.
10% B	4.33	8.15 c.c.	13.98 c.c.

Plasma + Saline	7.5	60.9	
Plasma + A	5.96	6.9	
Plasma + B	5.51	5.8	

whom 400 c.c. of 10 per cent amino acids was given intravenously during a period of two hours and thirty minutes. Variation in CO_2 combining power and pH of plasma did not exceed the limits of experimental error.

From these in vivo studies it is apparent that hydrolyzed casein, in spite of its very appreciable hydrogen ion activity in vitro, has but little effect on the acid-base balance in the body. Since but a small proportion of this substance, given intravenously, is excreted as such in the urine, and since there is but little immediate destruction of the substance, as measured by increased ammonia excretion, it appears necessary to postulate the very rapid conjugation of parenterally administered amino acids in order to explain how the acidity of such solutions is nullified without affecting the alkaline reserve of the blood. That such conjugation of amino acids results in the immediate formation of complete proteins seems hardly likely although such a step may be a major one in the synthesis of protein. This conclusion is in harmony with direct observation on the rapidity with which the blood stream is cleared of injected amino acids.[12, 13]

To further test for toxic action of casein hydrolysate, post-mortem studies were made on seventeen patients who had received casein digest by intravenous route during the course of their terminal disease. Of these patients, the maximum

*These individuals were both adult women. Patient No. 1 had undergone a cholecystectomy, and patient No. 2, an appendectomy, the preceding day. They both made uneventful recoveries. These patients were on the service of Dr. Alexander Brunschwig.

†A 56-year-old white man suffering from lipoid glomerular-nephritis (nephrotic nephritis).

amount administered was 2,100 Gm., as 10 per cent solution (over a 21-day period). Time of administration of amino acids in these patients varied from twenty days to one hour before death. In no case were there morphologic changes in tissues which could be definitely attributed to a toxic effect of casein hydrolysate. In but one instance was there any reason to suspect that amino acid therapy was a factor in causing death. This was in a man with carcinoma of the cystic bile duct who had undergone an operation in which the gall bladder and cystic duct were resected, the common bile duct ligated, and the hepatic artery ligated and severed. Postoperatively, this patient's course was one of progressive failure. There was jaundice and, two days before death, a precipitous fall in serum protein. In an attempt to ameliorate this condition amino acid therapy was instituted. Following the intravenous administration of 200 c.c. of 10 per cent amino acid solution, the patient experienced a severe chill. The venous infusion was stopped, but the patient died an hour later. At necropsy severe hepatic damage was evident.

That the liver is the major organ concerned with the synthesis of protein seems evident from the work of Whipple, Mann, and others; in fact, the disappearance curve for injected amino acids has been used with some success in evaluating liver function. The study of intermediary protein metabolism with the aid of isotopes by Schoenheimer and others also lends support to the view that amino acids, plasma proteins, and tissues proteins, especially those of the liver, exist in a state of very dynamic equilibrium. In a recent paper,[14] Madden and Whipple summarize such experimental evidence and conclude, "The present evidence speaks in favor of the liver as the site of production of albumin and much of the globulin."

The case last cited may well represent a situation in which hepatic damage was so severe that rapid conjugation of amino acids, as a preliminary step in the synthesis of protein, could not occur, with the result that amino acids given intravenously exerted the same effect on the acid-base balance of the body as was observed in in vitro experiments with human plasma (see Table I). It suggests that marked hepatic insufficiency may be a very serious contraindication to the parenteral administration of amino acid mixtures.

SUMMARY AND CONCLUSIONS

It has been demonstrated that the two preparations of casein hydrolysate tested are nonantigenic. Reactions of normal smooth muscle strips to casein digests have indicated the presence of some histamine-like substances, peptones, or tyramine, which may explain the frequently observed reactions of flushing, sensation of warmth, and nausea, in patients administered casein hydrolysate by vein. It has been shown that although casein hydrolysates have a high hydrogen ion concentration and activity, this does not appreciably affect the acid-base balance in those persons with adequate liver function. This is presumably due to the very rapid rate at which amino acids are conjugated by the liver. Post-mortem studies of seventeen individuals who had received casein digest parenterally failed to disclose significant morphologic changes as a toxic manifestation of amino acid therapy. The suggestion is made that patients with poor liver function may be unable to conjugate parenterally administered amino acids at a sufficiently rapid rate to escape severe acidosis.

CAFFEINE-WITHDRAWAL HEADACHE*

Robert H. Dreisbach, Ph.D., and Carl Pfeiffer,† Ph.D., M.D., Chicago, Ill.

THE production of the experimental headache for investigative purposes was initiated by the observations of Loevenhart[2] and his co-workers in 1927, who found that nitrite headaches were accompanied by a dilatation of the meningeal blood vessels. Pickering[3] in 1933 studied headaches produced by the intravenous injection of small amounts of histamine. These studies were enlarged by Clark et al.[4] in 1934 and by Wolff et al.[5] in 1940, who demonstrated that this experimental headache was accompanied by an increased excursion of the cerebral blood vessels. Carbon monoxide headaches have been studied in a few individuals (Cobb et al., 1924),[6] but the toxic nature of carbon monoxide does not lend itself to human experimentation. The experimental headaches studied thus far do not simulate any of the so-called common headaches in mode of onset or duration. The histamine headache, however, is by far the most constant and may be produced in almost all subjects.

Because many people ascribe an occasional headache to lack of their morning coffee, and because considerable "letdown" must result if this stimulant drug is withdrawn from habituated individuals, an attempt to produce and study such a headache was undertaken. In a recent survey of one hundred and twenty-eight migraine patients, twenty-five stated that lack of their usual coffee intake would result in headache. Five patients volunteered the information that the headache was not of the migraine type. In this study we have attempted to produce headache by administration of caffeine over a suitable period, usually a week, and then abruptly withdrawing the drug.

Data obtained in this laboratory[7] have indicated that there is a relative hemoconcentration accompanying migraine. Hence, it was thought advisable to determine total proteins and hematocrits during the course of the experiments. Several investigators[8-11] have reported that the serum calcium is decreased in migraine patients. Therefore, it was thought possible that electrolyte changes in the blood might also be correlated with any period of headache produced by caffeine withdrawal.

EXPERIMENTAL

Caffeine, 0.120 Gm. capsules (gr. ii) as the sodium benzoate or citrate salt, was administered to normal subjects in an increasing daily dosage up to 0.78 Gm. (gr. xii), usually given in the morning. Twenty male and two female subjects (graduate and medical students) were used. Their ages varied from

*From the Departments of Pharmacology of the University of Chicago and Wayne University Medical Schools.

A preliminary report was given before the American Society for Pharmacology and Experimental Therapeutics at New Orleans, March, 1940.

Aided in part by a grant from the Committee on Therapeutic Research of the Council on Pharmacy and Chemistry of the American Medical Association.

†Lieutenant (M.C.), U.S.N.R.

Received for publication, November 16, 1942.

20 to 33 years. They were *not* hospitalized, but they were observed and had their symptoms recorded daily. No regulation of food intake was attempted. Only three of the twenty subjects were normally total abstainers from caffeine-containing beverages. In order to add to our knowledge of the migraine syndrome, five of the subjects were particularly chosen because they had had typical periodic migraine headaches for at least two years. The subjects were given a series of ten or more dated envelopes, each containing the same number of capsules, placebo capsules and caffeine capsules being mixed in such a way that the subject would start with a small dose of caffeine the first day, but increasing daily so that by the sixth or seventh day the subject would be receiving 10 to 12 grains of caffeine per day. On the seventh or eighth day placebo capsules were substituted without the subject's knowledge, so that no caffeine was received thereafter. During the experiment the subject abstained from caffeine beverages, and in most cases the subjects had no caffeine beverages for the 24 to 48 hours preceding the beginning of administration. The experiment was postponed if the subject had a headache, and this occurred in five instances when habituated subjects discontinued their customary daily coffee intake.

Five blood samples were taken during each experiment. An initial control sample was taken before administration of caffeine was started, a second at the height of the caffeine stimulation, a third on the day before withdrawal, a fourth at the height of the headache, and a fifth on the following day when the subject was free of headache. In tabulating the results, the first three samples on each subject have been averaged, since they were found to be uniformly the same. At the time the blood samples were taken, blood pressure and pulse were recorded after the subject had been supine for five minutes. All control observations and samples were taken between 4 P.M. and 8 P.M. after it was found that this was usually the time of maximum headache.

Serum calcium, serum inorganic phosphorus, serum potassium, serum protein, serum and blood specific gravity, and hematocrits were determined as in previous studies.[12] The calcium samples were stored at a stable phase of the analysis, so that fifty to one hundred samples could be disinterestedly titrated.

RESULTS

During the first two or three days of caffeine administration, all subjects reported stimulation with slight muscular tremors and a lessened sense of fatigue. Two subjects noted insomnia immediately upon retiring, but this was never severe enough to require sedation. Later they noted no stimulation, but did report that they slept longer and more soundly. Approximately one-half of the subjects reported diuresis during the early period of the administration. The lack of stimulation on repeated doses agrees with the findings of Eddy and Downs,[13] who noted an increase in the reaction time in habituated subjects.

In twenty-one out of thirty-eight trials, headache resulted which was as severe as the subject had ever had. In eleven trials the headache was definite, but not severe enough to necessitate treatment. In six experiments on four subjects very slight or no headache resulted. The headache-resistant group did not include any of the original abstainers from caffeine. In three of these re-

sistant subjects, the icteric index was above the normal range[23, 11, 8] and the sclerae of M. B. with an index of 23 were yellow-tinged. These three subjects have noted that they are generally free of headache of any type. However, subject M. B. with idiopathic jaundice had a typical histamine headache of 12 minutes' duration when given 0.1 mg. of histamine diphosphate intravenously. Both of the two female subjects developed severe headache which required treatment.

Characteristics of the Headache: The symptomatology of the headache is remarkably constant and may be summarized as follows: On the day of withdrawal, lethargy was usually noticeable in the morning, while a feeling of cerebral fullness occurred about noon. Actual headache usually began in the early afternoon and reached a peak three to six hours later. The subjects localized the headache as occipital or central at the onset, which then in most cases became generalized and throbbing in character. In six subjects the headache was consistently accompanied by some degree of nausea, and in two subjects vomiting occurred. In four subjects the headache was consistently accompanied by a serous rhinorrhea of such severity that they at first thought that an acute upper respiratory infection was impending. Subjects also complained of mental depression, drowsiness, yawning, and disinclination to work.

During the incipient stage of the headache the patients' ears were usually intensely hyperemic, but later if the patients became nauseated, the ears would pale and generalized pilomotor activity was observed. The headache, when well established, was intensified by bending over or by straining, as at stool (Valsalva's experiment). Relaxation, such as napping, made the headache worse, while violent physical exercise (running upstairs), with the exception of one subject, intensified the headache. Jugular vein compression with the resultant increase in cerebrospinal fluid pressure produced the usual feeling of cerebral fullness, but did not intensify the headache.

Treatment of the Headache: Headache produced by caffeine withdrawal was found to respond to treatment by caffeine or acetylsalicylic acid. When caffeine was used to relieve the headache, the subjects sometimes complained of secondary headache the next day. While benzedrine sulfate gave relief for two to six hours, in four of six subjects the headache recurred in an intensified form. Amyl nitrite afforded temporary relief in one subject, but this was then followed by a short period of exacerbation, after which the headache continued as before. In severe headache with nausea and vomiting, oxygen inhalation afforded definite relief in two subjects. If given early enough in the course of the headache, the most effective treatment was caffeine.

Blood Findings: In Table I are given the results of determinations of serum calcium, serum inorganic phosphorus, serum protein, and hematocrit during the normal and administration periods, at the time of the headache, and on the day following when the subjects were free of headache or had received caffeine in treatment of a secondary headache. Under each column are given the averages and standard deviations of all the data. Values obtained during the administration of caffeine are not tabulated separately because these values were comparable to the normal values. The serum protein and the hematocrit were found to be generally lower at the time of the headache in all but three

experiments. The serum calcium was lower in all but one experiment, and serum inorganic phosphorus was slightly higher during the headache period. The change in serum calcium could be ascribed to the hemodilution except that by the same reasoning the rise in serum phosphorus would be even greater than is apparent from the data. Since calcium fluctuates inversely with phosphorus, the calcium may still be indirectly involved.

Graphs of changes in blood constituents in one subject during three different experiments are shown in Figs. 1 to 3. It should be noted that at the time of the headache, significant, but not consistent, decreases occurred in the serum calcium, protein, hematocrit, and blood specific gravity. An elevated serum phosphorus was consistently present at the time of the headache. The blood pressure and pulse changes were frequently marked, but were in general uninterpretable.

The first column in each series represents the average of all determinations taken before the headache. Column 2 represents determinations at the time of the headache, and column 3 represents determinations 24 hours after the headache. The mean of 12 control calcium samples taken daily at 5 P.M. on 4 subjects for 3 days was 9.45 ± .57 mg. per cent.

DISCUSSION

It was uniformly noted that the headache following caffeine withdrawal was quite different from the migraine syndrome in the five migraine subjects studied, although the caffeine-withdrawal headache was accompanied by nausea in four of the migraine subjects and vomiting in one. In two subjects whose migraine is typically unilateral the caffeine-withdrawal headache was generalized. In two subjects the headache occurred on the opposite side of the head from their usual migraine. One subject has left-sided frontal migraine, but three caffeine-withdrawal headaches were bilateral and occipital in distribution. Three of these five subjects regularly have scotomas with their migraine headaches, but no such visual phenomena preceded or accompanied this experimental headache. Two migraine patients, however, had migraine headaches at the height

of the stimulant action of caffeine, and in one of these subjects this again occurred when another caffeine-withdrawal headache was attempted. It would thus appear that the true migraine headache is apt to occur during the period

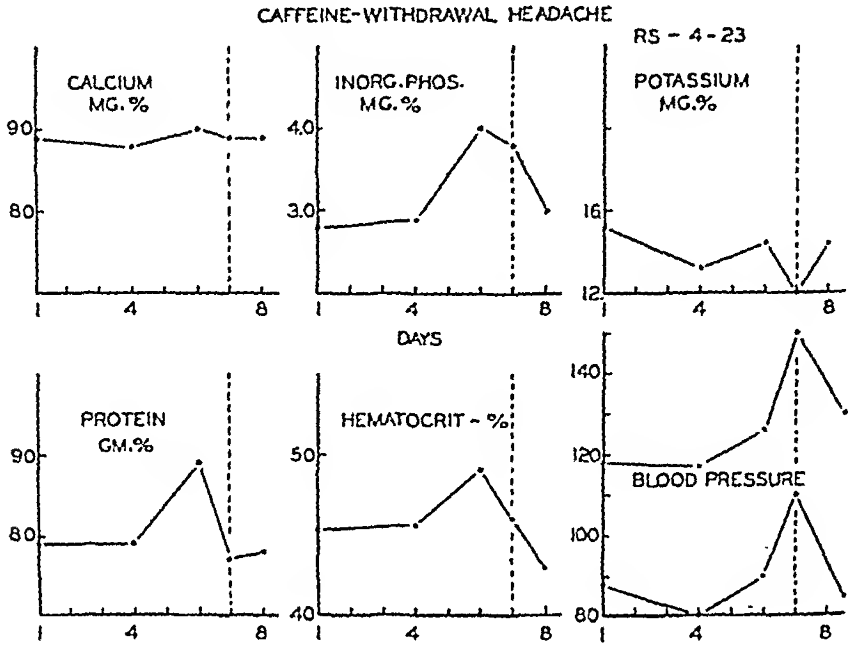

Fig. 1.

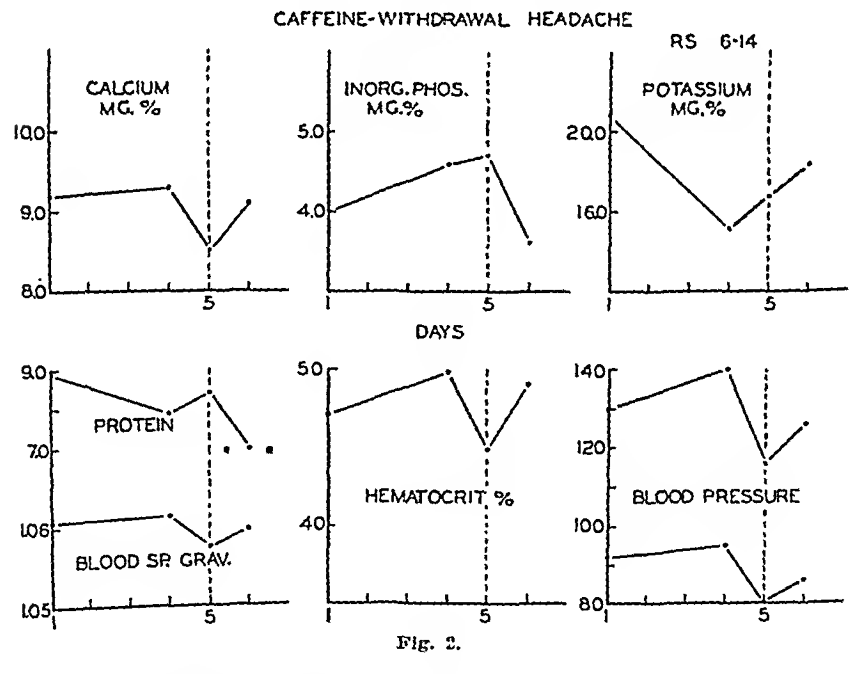

Fig. 2.

of caffeine overstimulation,* while the withdrawal of caffeine results in a distinct type of generalized headache. In a recent study[7] of migraine headache, we found no consistent changes in the serum calcium or phosphorus. A slight

*This led to an erroneous statement in the original Proceedings report.[1]

rise in hematocrit and total proteins was present at the time of the headache. The change in blood chemistry and blood volume found in this study would, hence, be another point of dissimilarity between the two types of headache.

That the caffeine-withdrawal headache is due to changes in cerebrospinal fluid pressure or volume is doubtful, since bilateral jugular compression which raises cerebrospinal fluid pressure does not intensify the headache. Amyl nitrite, however, relieves the headache during the short period of relaxation of the peripheral and splanchnic vascular tone. While the present data, due to the inadequacy of present methods, must necessarily be inconclusive, there are numerous findings that would be in accord with the hypothesis that this headache might result from an increase in effective arterial blood volume without a corresponding diminution in peripheral vascular tone, namely, the gradual onset of cerebral fullness, hyperemia of the ears, lowered serum proteins, the occurrence upon withdrawal of a diuretic drug, and the response to drugs and physical measures affecting headache.

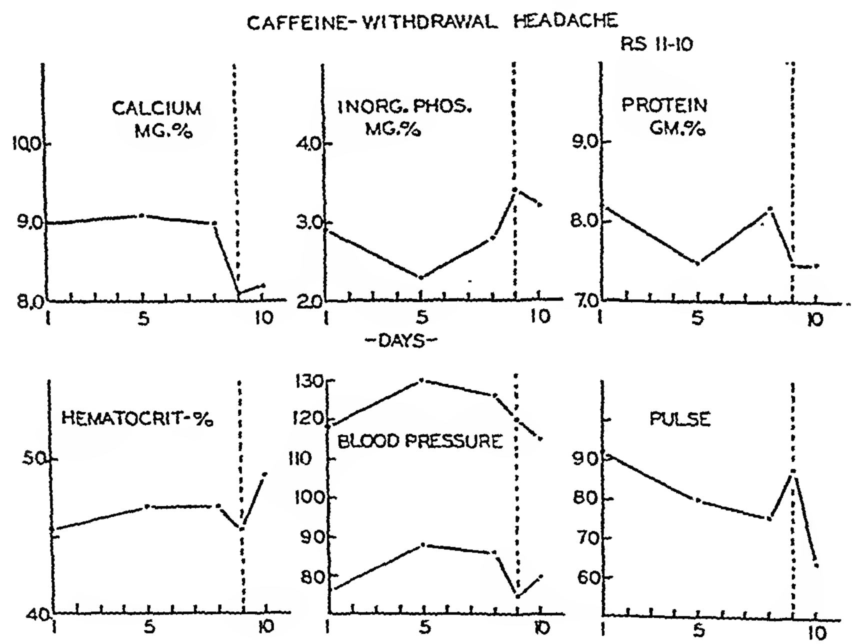

Fig. 3.

It is known from the work of Wolff[14, 15] that many headaches, including histamine and migraine headaches, are accompanied by an increased excursion of the cerebral blood vessels. This may occur reflexly or passively by changes in the volume or pressure of any one of the three semifluid media within the cranial vault, namely, the cerebrospinal fluid, the brain substance, or the blood. Since the first two media are relatively constant, and since the functional pathology of most headaches is known to reside in the vascular wall, the cause of the pain must be either a reflex dilatation of the blood vessels or an increased excursion of the vessels due to the two other factors which could affect the caliber of the cranial blood vessels, namely, the arterial blood volume or the pressure of the surrounding media. Bazett[16] has estimated the *arterial* blood volume from

anatomic measurements of the mesenteric vessels, and his observations indicate that the arteries probably contain a relatively small proportion (perhaps less than 20 per cent) of the total blood in a given region of the circulation. Thus, while the changes in blood volume demonstrated in this study are small, they may have exaggerated significance when combined with changes in cardiac output and peripheral vascular tone.

Since all factors must be considered, there remains the possibility that this headache might be due to direct or reflex dilatation of the cerebral vessels by the withdrawal of caffeine. Hirschfelder[17] has shown that caffeine tends to dilate the cerebral vessels if given intravenously. Oral caffeine is, however, believed to constrict the cerebral vessels, and this has been correlated by Sutherland and Wolff[18] with the observation that caffeine decreases the excursion of the cerebral blood vessels when used in the treatment of migraine headache.

The caffeine-withdrawal headache probably typifies one of the so-called "common headaches." In this respect it may be of value as an experimental headache. It may also provide a means of studying analgesic drugs by affording a method of producing predictable headaches. This study also provides a plausible explanation for the hitherto empirical addition of caffeine to many headache remedies.

The authors wish to express gratitude to the numerous subjects who aided in these experiments.

SUMMARY

In 55 per cent of thirty-eight trials on twenty-two subjects, headache as extreme in severity as the subjects had ever experienced was produced by the sudden withdrawal of caffeine. In 29 per cent of the trials the headache was definite, but did not require treatment. In 16 per cent of the experiments little or no headache resulted. The headache is without scotomas, slow in onset, central in origin, becoming generalized after four to six hours; and it may be accompanied by nausea and vomiting. In migraine subjects the headache differs from their typical migraine headache. The blood studies indicate that a lowered serum calcium, an elevated serum phosphorus, and possibly an increase in blood volume accompany the headache.

THE ETIOLOGY OF THE MIGRAINE SYNDROME—A PHYSIOLOGIC APPROACH*

CARL PFEIFFER,† PH.D., M.D., ROBERT H. DREISBACH, PH.D., CHARLES C. ROBY, PH.D., AND HOWARD G. GLASS, B.A., CHICAGO, ILL.

THE possibility that blood volume changes might participate in the etiology of migraine headaches has not hitherto been investigated, although Lennox and Leonhardt[1] in 1937 suggested that alterations of "blood concentration" might play a dominant role in migraine headache. Established factors in the migraine syndrome which might be correlated with changes in blood volume are:

1. Onset at puberty and frequent relief at the menopause (correlating with onset and waning of cyclic activity of the sex hormones with their salt- and water-retaining properties).

2. Greater incidence in the female than in the male due to greater salt- and water-retaining power of estrogens compared to androgens.[2]

3. Menstrual migraine (perhaps due to sudden decrease in the estrogens with their salt- and water-retaining activity).

4. Relief of migraine by pregnancy due to the normal, concomitant increase in the blood volume with a high, maintained estrogen level.

5. Partial relief of the headache by the coal tar analgesics[3] and thyroid[4] therapy, both of which are known to produce a relative hydremia.

6. Marked relief by long-acting vasoconstrictor drugs, such as ergotamine tartrate and benzedrine sulfate (amphetamine).

*From the Departments of Pharmacology of Wayne University and the University of Chicago Medical Schools.
†Lieutenant (M.C.), U.S.N.R.
Received for publication, November 16, 1942.

7. The occurrence of the headache with relaxation or a relative "let down" in activity.

These factors might be ascribed to an accompanying relaxation of peripheral-vascular tone without an increase in blood volume. Any altered physiology due to hereditary anomalies of the cerebral arteries would be precipitated at this time because of the decreased blood supply to the cranial area. It was the purpose of this study to determine whether headache of the migraine type is accompanied by relative changes in blood volume; at the same time other data, such as the blood pressure, pulse, serum calcium, phosphorus, and potassium, were obtained.

EXPERIMENTAL

1. *Relaxation Headache.*—The typical Sunday morning headache of the business man, the Monday headache of the clergy, the day-off headache of the nurse, and the post-examination headache of the student may all come under this classification. In order to determine if blood volume or electrolyte changes were involved in relaxation headaches, medical and graduate students were asked to come to the laboratory for blood sampling whenever they had a spontaneous headache. At that time a careful history was taken of the preceding sequence of sleep and activity to correlate any possible relaxation factor. In a series of twenty-six headaches studied, nine could be definitely correlated with relaxation (such as sleeping late). Blood samples were taken and analyzed for serum calcium, potassium, inorganic phosphorus, and proteins. The pulse, the reclining blood pressure (average of 3 to 4 trials), and hematocrits were also determined. A second series of observations and samples was taken after relief of the headache by caffeine and acetylsalicylic acid. If this therapy did not relieve the headache, the second blood sample was not obtained until one or two days had elapsed. Table I summarizes the findings in the nine headaches in which the subjects gave a history of relative relaxation. Ordinarily the serum proteins are the best index of changes in the blood volume, since they are usually constant. A rise in the serum proteins indicates a decrease in the blood volume at the time of the headache. Conversely, a lowered serum protein indicates a hemodilution. The hematocrit is much less reliable because it is changed by mobilization or storage of the red blood cells.

It is of interest to note that half of these subjects with relaxation headache have an appreciable rise in diastolic blood pressure at the time of the headache. With only two exceptions the change in the serum proteins indicates a relative hemoconcentration at the time of the headache. In the case of B.V. the first headache followed sleeping late after a hurried week-end motor trip. Accordingly, the same degree of sleepless activity was again artificially simulated, and the subject again slept late. Except for the blood pressure and the degree of the headache, the findings were almost identical. The first headache was, however, more severe, which happening might in some way be associated with the higher diastolic blood pressure.

2. *Migraine Headache.*—In a similar fashion, blood samples were obtained from migrainous patients suffering from typical migraine headache. Table II summarizes the findings in ten such headaches. These observations differ from

the findings in the relaxation type of headache in that five subjects showed a marked hypotensive level of blood pressure at the time of the headache with a return to normal on relief of the headache. The other six showed higher serum protein levels, thus indicating relative hemoconcentration at the time of the headache. In those cases that had no actual volume change, a relative inadequacy of the effective arterial blood volume is suggested by the decreased blood pressure, indicating a decreased peripheral-vascular tone. There was evidence of a lengthened blood-clotting time during the headache.

3. *Menstrual Migraine.*—A few patients with menstrual migraine have two types of headache. The first is a dull, generalized headache which may occur during the week preceding menstruation at the height of the estrogenic salt and water retention and may be due to a relative hemodilution. The second type, a typical migraine syndrome, occurs around the first day of menstruation and is perhaps due to the quick rebound phenomenon described by Harrop.[2] Table III summarizes the findings in five menstrual migraine headaches. It is evident again from these data that the only common factor at the time of the menstrual migraine headache is a decreased blood volume as indicated by a relatively higher serum protein level at the time of the headache. The subject

A. U. is of interest in that the menstrual migraine is accompanied by the same lowering of blood pressure which characterized a previous migraine attack that did not occur at menstruation. The average hematocrit is distorted by the final normal sample in No. 5 which was obtained two weeks after the headache. Menstrual blood loss might also affect the hematocrit readings at the time of the headache.

DISCUSSION

While the extensive studies of Graham and Wolff and their colleagues[5] have indicated that cerebral pain is vascular in origin, they have not explained why the cerebral arteries should suddenly start dilating or why ergotamine, which acts mainly on the peripheral blood vessels, should decrease the excursion of the cerebral blood vessels. Our studies indicate that the excursion of the cerebral blood vessels may be traced to changes in arterial blood volume without compensatory changes in the peripheral vascular tone.

†Gm. per cent ± Standard deviation.

The numbers in parentheses represent the number of subjects and patients used in compiling the respective means. The change in serum calcium and phosphorus found in subjects with caffeine-withdrawal headaches does not occur in migraine headaches. The blood volume trend, as judged by the changes in the hematocrits and serum proteins, is opposite in the two headaches.

In 1927 Loevenhart et al.[6] postulated that headache could arise from changes in volume or pressure of any one of the three fluid or semifluid media within the rigid confines of the skull. They defined these three semifluid media as the blood, the brain, and the cerebrospinal fluid. Headache resulting from changes in the volume of the brain and cerebrospinal fluid is well known and self-explanatory. In order to complete and clarify the discussion, we have summarized in Fig. 1 the known hydrodynamic factors which might possibly be involved in all types of headache. The pain-sensitive structures within the cranial vault, namely, the cranial blood vessels (arteries and veins), the dura, the tentorium cerebelli and the falx cerebri, are depicted. The various fluid pressure forces which might cause an increased excursion of the blood vessels or an abnormal stretch of the supporting membranes are also represented. Since the headache due to changes in cerebrospinal fluid volume and actual

brain volume is self-explanatory, the discussion will be limited to the changes in effective blood volume and peripheral vascular tone. While known data are not available on effective blood volume or cardiac output changes in nitrite or histamine headache, it is suspected that since these headaches do not occur

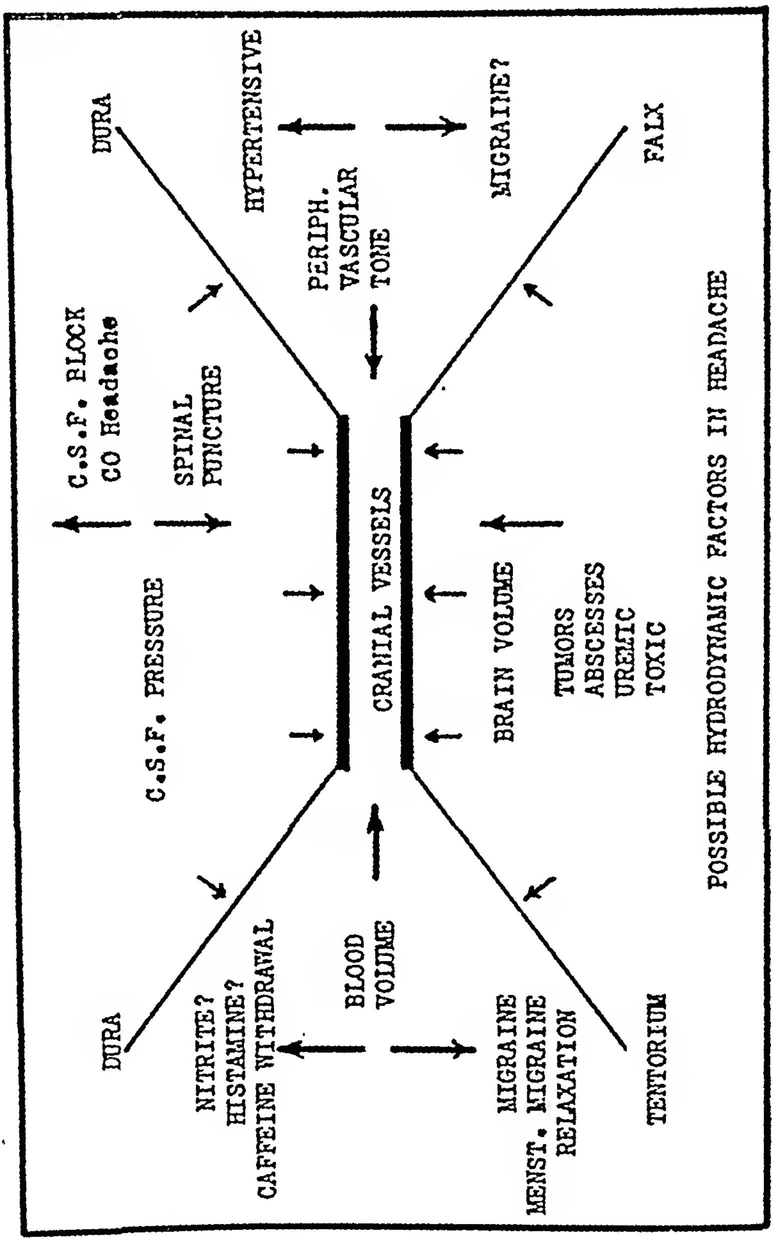

Fig. 1.

at the time of the hypotension from the drugs, they may be connected with the rise in blood pressure following the period of hypotension. If an increase in cardiac output occurs during the hypotensive period, the headache could be caused by a relative increase in the effective arterial blood volume at a time when the peripheral blood vessels are constricting. The data on "caffeine-withdrawal" headache[7] support the theory that this type of headache is accom-

panied by a relative increase in the effective blood volume. Conversely, these studies have substantiated the hypothesis that headache of the migraine and relaxation types is accompanied by a relative diminution in the blood volume.

Hypertensive patients are known to be frequently afflicted with so-called "tension headache." Experimental subjects in this laboratory have experienced similar headache with large doses of ephedrine or neosynephrin. It has been our experience that severe, persistent, frontal headache (occasionally with nausea and vomiting) occurs when normal subjects are given intramuscular doses of neosynephrin HCl in excess of 10 milligrams. This is relieved temporarily by inhalations of amyl nitrite; but complete relief does not occur until the blood pressure returns to normal. This could be accounted for by a sudden increase in peripheral vascular tone without an equal diminution in effective blood volume and cardiac output. A portion of the data in this study supports the theory that some migraine headaches may be accompanied by a marked decrease in peripheral vascular tone, and this is reflected in the semi-shocklike level of blood pressure obtained at the time of the headache.

The treatment of migraine headache should, then, be directed at increasing the blood volume or restoring an intense peripheral vascular tone by strong smooth muscle stimulants, such as ergotamine tartrate or amphetamine sulfate. When this is effectively accomplished, the excessive excursion of the cerebral blood vessels subsides with subjective relief.

SUMMARY

Data are presented which justify separation from the so-called "common headache" of two new types, namely, relaxation headache and "caffeine-withdrawal headache." The former is accompanied by a decreased blood volume, and the latter may be ascribed to a relative increase in the effective arterial blood volume. No consistent blood electrolyte changes occur with relaxation or migraine headache. The determination of the serum proteins and hematocrit during and after migraine headache indicates that the migraine syndrome is accompanied by a relative hemoconcentration. Many other known factors in this syndrome can be correlated with changes in blood volume and peripheral vascular tone.

CHRONIC BRUCELLOSAL TYPE OF ANKYLOSING SPONDYLITIS

E. GOLDFAIN, M.D., OKLAHOMA CITY, OKLA.

DURING the past four years routine tests have been done on a number of patients with ankylosing spondylitis who came to the office for treatment. These tests, in addition to others, consisted of agglutination and opsonic index and skin test for brucellosis, bacterial complement fixation test with several strains of streptococcus antigens, especially hemolytic, viridans, nonhemolytic, and alpha prime *Streptococcus viridans;* and skin tests with a number of streptococcus strains, such as the hemolytic, viridans, alpha prime viridans, nonhemolytic, and anhemolytic streptococcus types.

In all there have been eighteen cases of *ankylosing spondylitis.* Of the eighteen patients two were women, indicating the usual ratio observed in ankylosing spondylitis of male to female, approximately 8 to 1.

Five patients gave quite positive skin, agglutination, and opsonic index tests for brucellosis. Rather interesting it was that those who gave strongly positive brucellosis tests in general gave essentially negative results on being tested for streptococcal antibodies and by skin test. Each patient had had his symptoms for quite some period of time. A diagnosis of ankylosing spondylitis was based upon a characteristic history, proper physical findings, and the demonstration by x-ray of changes in the vertebral ligaments indicative of ankylosing spondylitis, as well as of sacroiliac joint involvement.

Agglutination tests for brucellosis were carried out by the rapid plate method. The opsonic index test was done according to the method as elaborated by Huddleson and others; the skin test was carried out by injecting 0.1 c.c. of normal salt solution containing 10 million brucella organisms.

Streptococcal antibody tests were done in each case. It was felt that streptococcal skin tests should be performed in such a way that there would be no question, when a positive reaction was obtained, that definite hypersensitivity as a result of either past or present infection against the streptococcal strains was present. One-tenth c.c. of normal saline solution containing 10,000 organisms of the streptococci was injected intradermally, and observation of the skin test reaction was carried out over a period of at least forty-eight hours to as much as seventy-two or ninety-six hours.

A red cell sedimentation test was done in every case.

A review of the literature in respect to complications of either acute or chronic brucellosis, but especially of chronic or convalescent brucellosis, revealed some very pertinent findings in the foreign and American literature.

W. A. Bishop, Jr.,[1] makes some of the following important observations and quotes an extended review of the literature in his article. The result of his survey reveals:

Received for publication, November 16, 1942.

[1]J. Bone & Joint Surg. 21: 665, 1939.

1. "Spinal localization is the most common bone and joint complication of brucellosis."

2. "Localization may appear during any phase of the disease. Localization may be independent of a history of previous ailment. Localization as a complication is more common in the convalescent period."

3. He quotes Serio: "Local recurrence of the brucellosis is probably due to a lack of immunization to the organism."

4. "Localization occurs most often in the lumbar area."

5. "Frequent locomotor symptoms of chronic brucellosis are those of arthralgia, joint effusion, joint swelling, or a combination of arthralgia, joint effusion and joint swelling."

6. "The pathology has usually been described as an epiphysitis. Abscesses of vertebral bodies and/or vertebral discs have been described."

Bishop also quotes:

"Under pathology Feldman and Olson described in the hog irregular abscesses in the vertebral bodies and intervertebral discs. They were able to recover the organisms from ten of these cases. They described 0.5 to 3 cm. grayish-white, thick, pasty or caseous localized areas and occasionally sequestra. Certain lesions presented a crescent-shaped caplike inflammatory proliferation of osteogenic tissue bridging the intervertebral space on the ventral surface of the affected vertebrae. They concluded that the amount of ossification is variable depending on the duration of the lesion."

Bishop—"Their gross description of these lesions in hogs is compatible with the x-ray picture in human cases."

Bishop also quoted Serio as stating that chronic bony spurs on the anterior surface of the vertebral bodies would be noted as a part of the pathology and that occasionally calcification changes in focal areas would appear in the vertebral bodies instead of decalcification as is seen in tuberculosis. In other words, a characteristic zone of sclerosis instead of demineralization may occur at the original site of a brucellosis focus.

Bishop—"Serio states that these sclerotic changes accompany the infiltrative process, which infiltrative process gradually extends and may involve the entire vertebral body, and at times various processes of the vertebrae." Bishop also quotes: "There is variability of site and extent of lesions of the brucellosal complications in the spine. They may be confined to the disc and yet no narrowing of the disc or only very mild narrowing of the disc may occur. Often the vertebral body is normal or it may often be sclerotic or irregular. The original lesion may be masked by concomitant periosteal reaction, such as lipping or spurs on the anterior margin of the vertebrae." Bishop also makes specific mention from the literature of the fact *that occasionally an anteroposterior view of the spine will show the sclerotic processes following the contour of the intervertebral disc.* He also states that in cases in which the condition is more advanced constant and characteristic x-ray changes may be present as follows: "That all showed a reactive change, increased calcification of the bodies, circumscribed or diffuse, with proliferation of bone spurs across the interspace. Occasionally in the more severe cases deformity of vertebral body or *involvement*

of the articular facets will occur. Bony fusion of the bridges between the adjacent bodies is a common finding."

Bishop further quotes: "Hardy and Simpson, independently of each other, reported that one-third of patients with brucellosis had severe arthralgia. Straehm, in a thesis on an epidemic of undulant fever reported occurring in South Africa in 1911, recorded 268 cases in which joint swelling and effusion occurred in 15.3 per cent."

The symptoms of ankylosing spondylitis as a complication to chronic brucellosis are those of a case of infectious spondylitis in which pronounced rigidity of the spine, either locally or throughout its entire extent, plus either local or diffuse muscle spasm, will be present. Rigidity of the spine is especially present if the intervertebral articulations are involved.

The diagnosis of ankylosing spondylitis due to brucellosis must be based upon the history of back pain in patients who have had brucellosis in the past, in those who have some of the symptoms of chronic brucellosis, or in those who give strongly coordinated laboratory and skin test findings indicating the presence of either past or present chronic brucellosis. The agglutination and opsonic index tests are very important, especially the agglutination test. Often, as in other illnesses, the agglutination test may be negative or only very slightly positive, even though the disease process is present in the individual. The skin test should always be strongly positive, though cases are reported where a long-standing case of chronic brucellosis complication may have a negative skin test. The white blood cell count is usually normal or low. The patients may or may not have a temperature. The sedimentation rate may be accelerated. There should be negative findings for typhoid, if symptoms are acute, and negative findings for tuberculosis.

Of course the recovery of the organism from the lesions is the most important confirmatory finding that could be had. But its attempted recovery from chronic cases affords essentially a marked lack of positive results. It is a difficult procedure at the very best to recover organisms from a chronic brucellosis case. The usual findings that are present in a case of ankylosing spondylitis should be present, usually in a male, in the 15-to-45-year age group, with evidence of involvement of the sacroiliac and apophyseal joints, and the presence of calcification of some parts of the spinal ligaments or sacroiliac joints.

The development of the disease syndrome can be divided into three phases, the first phase being that of inexplainable symptoms and known as the prespondylitic phase; the second phase being one in which sacroiliac joint involvement can be demonstrated; and the third phase that in which definite and marked spinal rigidity is noted. The x-ray should be positive during the second and third phases. It will be negative during the first phase.

PATHOLOGY

Gunnar Edstrom[2] quotes the pathology of ankylosing spondylitis as being a chronic synovitis and tendinitis with round cell infiltration, hyperemia, and proliferation of the connecting tissue. These pathologic findings could be noted in any instance of an infection, whether such infection be by one or another known or unknown organism.

[2]Acta med. Scandinav. 101: 396, 1940.

T. Lloyd Tyson[3] describes the pathology as "a primary synovitis of the intervertebral joints with subsequent calcification of the ligamentous structures and eventual rigidity of the spine." The synovitis of the small intervertebral joints may be accompanied by osteoporosis of the vertebral bodies. There is present also at all times synovitis of the sacroiliac joints. Synovitis of the costovertebral joints may be present. Later calcification of the long ligaments, of the ligamentum flavum, and the ligaments at the lateral border of the intervertebral discs will occur. He states that the pelvic and shoulder girdles may be affected. He notes especially that the small joints, when they are involved, are of a typical rheumatoid arthritis involvement. This observation was also reported, in the instance of two cases, by Goldfain.[4]

Jacques Forestier,[5] under the heading "The Importance of Sacro-Iliac Changes in the Early Diagnosis of Ankylosing Spondylitis," states: "Atrophic arthritis of the joints between the facets of the vertebrae in the inflammatory stage is followed by bony ankylosis." Later ossification of adjoining ligaments (ligamenta flava) and anterior and posterior vertebral ligaments occurs. He stresses the importance of noting by x-ray the presence of early changes in the sacroiliac joints. His description of the x-ray changes in the sacroiliac joints would seem to be the description of changes that are often seen in joints having rheumatoid arthritis type of pathology; namely, first there appears marginal decalcification, later there appear pyknotic formations, and finally in the last stage total synostosis.

COMMENT ON CASES QUOTED—TABLE I

CASE 1.—C. A. W. This patient lived in a small Oklahoma town where pasteurization was poorly practiced. There was a lack of other findings except a very small infected tonsil

[3] M. Clin. North America 21: 1755, 1937.
[4] J. Lab. & Clin. Med. 27: 168, 1941.
[5] Radiology 33: 389, 1939.

remnant tissue, the removal of which did not help his symptoms. Improvement took place on general medical measures and bacterine therapy.

CASE 2.—R. E. R. The patient's home was in a small town in the panhandle of Texas, where no pasteurization of milk was practiced. In this case 44 tests for three strains of streptococci were present; however, the presence of strongly positive agglutination, opsonic index, and skin tests for brucellosis, plus long duration of trouble and suggestive positive history, justified labeling this case as due to brucellosis.

This patient did not respond well to bacterine therapy.

CASE 3.—G. G. The history of long continued illness, lasting several years, with episodes of fever, residence in a small town in the past, presence of same condition in a brother whom I examined but did not treat, plus strongly positive opsonic index, agglutination, and skin test for brucellosis justifies listing the patient as brucellosal spondylitis, ankylosing type. She responded quite well to bacterine therapy.

CASE 4.—C. B. This patient was living on a farm when his rheumatism began with arthralgias. Removal of his tonsils did not help. Loss of weight and weakness were prominently present. The negative antibody and skin tests for streptococci and strongly positive opsonic index and skin tests and moderately positive agglutination tests justify a diagnosis of chronic brucellosal spondylitis, ankylosing type. The patient's response to treatment has been only moderately favorable thus far.

CASE 5.—A. R. S. This patient lived in the panhandle of Texas. He lived on a farm. Milk was not pasteurized or boiled. His sister also had brucellosis. In a period of eighteen months on routine arthritic management and brucella bacterine his sedimentation test had become normal, and patient is free of symptoms.

CONCLUSIONS

1. Of eighteen cases of ankylosing spondylitis, five can be listed as being caused by chronic brucellosis in this series.

2. Ankylosing spondylitis is a symptom complex. The cause may be an infection which can be either determined, as apparently the five cases quoted could be, or nondeterminable in our present stage of knowledge.

3. Chronic brucellosis, like syphilis or tuberculosis, is protean in its manifestations. It may reveal itself in different ways. Apparently one of the complications of chronic brucellosis may be that of a rheumatoid type of arthritis, which when limited to the spine presents the symptom complex of ankylosing spondylitis.

THE SIGNIFICANCE OF THE GROSS CHARACTER OF THE SPUTUM IN THE PROGNOSIS OF PNEUMOCOCCIC PNEUMONIA*

Arthur W. Frisch, M.D., Alvin E. Price, M.D., and Gordon B. Myers, M.D.
Detroit, Mich.

RECENT studies concerning the important role of edema in the severity and spread of the pneumonic process in the lungs[5, 6, 9, 10, 11, 14] have stimulated our interest in the character of the gross sputum in pneumonia. At necropsy we noted a widespread, heavily infected zone of inflammatory edema in the lungs of patients who had produced large quantities of sputum during life. On the other hand, a narrow, well-defined edema zone at the periphery of the advancing consolidation was present in patients who raised small amounts of more tenacious sputum before death. On the basis of these observations the former cases were classified as "wet" lungs and the latter were designated as "dry" lungs. The characterization of cases as dry or wet lungs was then extended to include all pneumonia patients in whom the gross sputum was examined at daily intervals during the course of the disease.** In the present study of 651 cases, exclusive of Type III,† these findings have been correlated with the number of pneumococci per oil immersion field in Wright-stained smears of sputum,[1, 3] the type of pneumococcus, blood culture, leucocyte count, age of the patient, duration of the disease, the extent of involvement, and the outcome of the pneumonia.

---

*From the Departments of Bacteriology and Internal Medicine, Wayne University College of Medicine and Receiving Hospital, Detroit, Michigan.

Supported by a grant from the Commonwealth Fund to the Michigan Department of Health Laboratories.

Received for publication, November 25, 1942.

**The following report has been restricted to patients who produced rusty sputum. Satisfactory specimens were obtained from 90 per cent of the cases due to Types I through VIII; the remaining 10 per cent, who were either uncooperative or unable to produce rusty sputum, were excluded from the study.

†The outcome in Type III pneumonia is determined primarily by the amount of capsular polysaccharides formed in the sputum and lungs.[3, 4, 11]

METHOD

On admission to the hospital the patients were requested to cough and expectorate into a container. Observations concerning the ease of production and the quantity of sputum were made at the bedside. The specimens were then taken to the laboratory, examined under a strong light, and portions were removed for sputum counts in the manner previously described.[1, 3] The classification of patients as wet or dry lungs was usually, but not always, easy. Those patients who produced homogeneously rusty, watery to thin gelatinous sputum in considerable quantities and with relative ease on coughing were classified as wet lungs. Those who, upon vigorous coughing, raised small amounts of viscid sputum, which was either homogeneously rusty or mixed with mucoid or mucopurulent material, were called dry lungs. In dehydrated patients the final classification was deferred until adequate fluids had been administered. In borderline cases the consistency of the sputum was the chief factor in determining classification.

RESULTS

Studies of 678 cases of pneumococcic pneumonia reported in detail elsewhere[3] have shown that the fatality rate was only 2 per cent when the average number of pneumococci per oil immersion field in Wright-stained smears of sputum did not exceed 10 (Group A). The fatality was 9 per cent when the sputum count ranged between 11 and 30 per field (Group B), 30 per cent when 31 to 75 organisms were present (Group C), and 77 per cent when the number exceeded 75 per field (Group D). The relation of the gross character of the sputum to the microscopic counts and to the outcome of the disease is presented in Table I. The fatality rate was 6 per cent for all cases classified as dry lungs and 23 per cent for those designated as wet lungs. When the comparison was restricted to patients whose sputum counts fell within a similar range, the fatality rates for the dry and wet lungs were essentially the same and were primarily influenced by the number of pneumococci present; however, only 7 per cent of the dry and 41 per cent of the wet lungs had more than 30 pneumococci per field in their sputa. The close relationship between the sputum count and the character of the pneumonic exudate is further emphasized by a consideration of the percentage of total cases within a given sputum group which were classed as dry or wet lungs: thus 85 per cent of the cases in Group A were dry and 15 per cent were designated as wet lungs. Corresponding figures for Group B were 45 and 55 per cent; for Group C, 28 and 72 per cent; for Group D 2 and 98 per cent, respectively. The significance of these data will be discussed.

In a previous study[3] it was also found that type, qualitative bacteremia, leucocyte count, and duration of the disease before therapy were relatively unimportant factors in prognosis when compared with the number of pneumococci in the sputum. Since 80 per cent of the patients with more than 30 organisms per field were characterized as wet lungs, it seemed important to determine the relation between the gross sputum and other prognostic factors. In Table II the cases have been classified according to the presence or absence of bacteremia. Of the total group of 651 patients studied, 59 per cent were dry and 41 per cent were wet lungs. Among those with negative blood cultures, however, the in-

cidence of dry and wet lungs was 75 per cent and 25 per cent, respectively. These figures were reversed in the group with positive blood cultures, where dry lungs were found in only 26 per cent and wet lungs in 74 per cent. It would appear, then, that blood stream invasion may be dependent upon the formation of large amounts of exudate in the edema zone of the lungs.

Others	130	64	73	36
Totals	382	59	269	41

*Type III not included.

The relationship between the gross character of the sputum and the type of pneumococcus responsible for the disease is shown in Table III. A breakdown of the cases revealed that the percentage of dry and wet lungs in Types I, II, VII, and VIII pneumonia did not deviate significantly from the mean of 59 and 41 per cent, respectively. Thus there was no evidence from this study that the formation of large amounts of exudate in the lung is a property peculiar to certain types of pneumococci.

The relationship between leucocyte counts and the gross character of the sputum is presented in Table IV. Among the total group of 483 cases with leucocytosis the incidence of dry and wet lungs was 64 and 36 per cent, re-

spectively, as compared with 43 and 57 per cent in the 254 patients with leucocyte counts below 10,000 per cubic millimeter. These figures reveal that there is a definite trend toward leucopenia in wet lung cases, but the differences were too small to suggest that a deficit of leucocytes is the chief factor in the formation of the edema zone in the lung.

The relationship between the gross character of the sputum and the duration of the disease on admission to the hospital is shown in Table V. Only 33 per cent of the total cases were seen more than 96 hours after the pneumonia had developed. The incidence of dry and wet lungs, however, remained approximately the same irrespective of the duration of the disease. It was concluded from these data that the length of time the patient was ill played little, if any, role in the formation of large quantities of exudate in the lung.

TABLE IV

RELATION OF DRY AND WET LUNGS TO LEUCOCYTE COUNT

Totals	209	100	219	100	125	100	86	100	639	67	33

In a previous study[3] it was noted that the degree of involvement and the age of the patient were factors which significantly influenced the fatality rate independent of the sputum count. In the present study, a close correlation was observed between the character of the gross sputum and the extent of consolidation. The incidence of wet lungs was only 34 per cent in the cases with consolidation confined to one lobe as compared to 64 per cent in those with multiple lobe involvement. While the reversal of the percentages was significant (Table VI), it was felt that the multiple lobe involvement, like bacteremia, was the result of, rather than the cause of, the outpouring of exudate into the bronchi and trachea. In this respect the character and quantity of the exudate might have contributed to the higher fatality rate associated with multiple lobe involvement.[3]

An analysis of the gross character of the sputum with reference to age is presented in Table VII. The incidence of wet lungs increased from 32 per cent in patients below 30 years to 44 per cent in those between 30 and 54 and finally to 51 per cent in the older age group. The trend revealed by these figures suggests that the character and quantity of the pneumonic exudate depend to some extent upon the age of the patient.

DISCUSSION

The classification of cases according to the gross character of the pneumonic sputum is a simple procedure which appears to be of considerable aid in prognosis. An overwhelming majority of the patients with dry lungs showed less than 30 pneumococci per field (93 per cent), a negative blood culture (86 per cent), a favorable leucocyte response (83 per cent), and consolidation which was confined to a single lobe (85 per cent). The relatively mild nature of the pneumonia which could be predicted from the appearance of the gross sputum was further substantiated by the fact that 94 per cent of the patients recovered irrespective of therapy. On the other hand, 41 per cent of the cases which were designated as wet lungs showed more than 30 pneumococci per field in the sputum; 58 per cent had bacteremia; 34 per cent had leucocyte counts below 10,000; and 37 per cent had involvement of more than one lobe on admission to the hospital. The pneumonia in these patients was more severe as shown by the higher fatality rate (23 per cent). As a general rule the clinical response to sulfonamides was slower in the cases classed as wet lungs.

The observations of Loeschcke[9] first drew attention to the significance of the edema zone in the transfer of pneumococci from one portion of the lung to another. His findings were soon corroborated by other workers.[6, 10, 11, 14] The experiments of Robertson and Hamburger[11] were of special interest to us because

of their conclusion that the severity of experimental pneumonia in the dog was directly related to the wetness of the lung. They believed that "metastatic lesions occur only when the primary lesion is sufficiently edematous to permit escape of fluid exudate through its main bronchus into that of another lobe or lobes, the direction of flow being determined largely by gravity." The bronchi of animals severely ill with extensive pneumonia yielded considerable quantities of a fluid exudate containing from 5 to 50 billion organisms per cubic centimeter. On the other hand, the exudates from animals with well-localized lesions were usually viscid and contained relatively few pneumococci. From these observations, which were substantiated by our own necropsy findings, it seems likely that the amount and gross character of the sputum in human pneumonia reflects the slate of the lung, copious wet sputum indicating an extensive area of inflammatory edema, a dry sputum indicating a more localized lesion. Such a hypothesis furnishes us with a plausible explanation for the high incidence of bacteremia and multiple lobe involvement in patients who have wet lungs, since the presence of a large edema zone would permit adequate opportunity for blood stream invasion or for metastatic spread to other lobes. It seems to us that the wet lung is a more likely cause of bacteremia than the result of the blood stream invasion, as has been suggested by Kempf and Nungester.[7]

The question as to why one patient should produce large quantities of rusty sputum and another relatively little remains unanswered. While an increase in the proportion of wet lungs occurred with advancing age and with leucopenia, it was felt that these were accessory rather than primary factors determining the character of the pneumonic exudate. The close correlation between the number of pneumococci and the nature of the gross sputum may be interpreted in one of two ways. It is possible that the outpouring of fluid into the alveoli represents an allergic response to the presence of a few pneumococci,[7] thus creating an environment which facilitates the rapid multiplication of the organisms; however, it seems more likely that the amount of exudate is directly proportional to the quantity of edema-producing substance elaborated by the large numbers of pneumococci present in the lung. This concept is supported by (a) the work of Sutliff and Friedemann,[12] who demonstrated such an edema-producing substance in filtrates of young pneumococcus cultures, and by (b) the studies of Hamburger and Robertson,[6] in which either localized or diffuse edematous lesions were experimentally induced at will by varying the dosage of pneumococci. The solution to this problem must await further study.

SUMMARY

The gross character of rusty sputum in 651 cases of pneumococci pneumonia was correlated with standard prognostic criteria and the outcome of the disease. As a result of observations made at necropsy, those patients who produced small amounts of a viscid rusty sputum were classified as "dry" lungs, whereas those who raised large quantities of watery to gelatinous, homogeneously rusty sputum were classified as "wet" lungs. The pneumonia in the former group was relatively mild, while the disease in the latter group was considerably more severe, as shown by fatality rates of 6 per cent and 23 per cent, respectively, as well as by significant differences in the number of pneumococci

in the sputum, the extent of consolidation, and the incidence of bacteremia and leucopenia. It was concluded that the gross character of the sputum was of distinct value in the prognosis of pneumococcic pneumonia. The significance of the observations with reference to the pathology of the pulmonary lesions is discussed.

CLINICAL CHEMISTRY

THE COMPARATIVE ACCURACY OF THE CLOSED CIRCUIT BEDSIDE METHOD AND THE OPEN CIRCUIT CHAMBER PROCEDURE FOR THE DETERMINATION OF BASAL METABOLISM*

ROBERT C. LEWIS, PH.D., ALBERTA ILIFF, PH.D., AND ANNA MARIE DUVAL, PH.D.
DENVER, COLO.

SUFFICIENT data have been accumulated by the investigations of the Child Research Council at Denver to establish standards of basal metabolism on children between the ages of 2 and 16 years. The first report of this work by Lewis, Kinsman and Iliff[1] gives the results obtained prior to April, 1936, and presents tentative standards for both boys and girls from 2 to 12 years old inclusive. Since the appearance of this publication, the question has been raised as to whether these standards may be used when determinations are made with a bedside type of apparatus. No report of a comparison of the results obtained with a chamber procedure and with a bedside apparatus has been found in the literature, although several studies[2-4] have been made on adults both with the open circuit and the closed circuit methods but where a mask or a mouthpiece and a nose clip have been used in both cases. In the present study determinations of the basal metabolism of both children and adults made with an open circuit chamber procedure have been compared with those obtained with a closed circuit bedside type of apparatus.

The open circuit chamber method was that used to establish standards of basal metabolism on children of the Child Research Council. The procedure is fully described in the publication of Lewis, Kinsman, and Iliff.[1] It should be noted that with this method a 15 per cent protein metabolism has been assumed and that the calorific value per standard liter of oxygen, which varies with the respiratory quotient found, has been obtained by reference to the chart of Michaelis.[5]

The closed circuit apparatus employed was a No. M 84 McKesson Metabolor, to which the subject was connected by means of a mask (face inhaler) or with a mouthpiece and nose clip. A McKesson face inhaler, a McKesson mouthpiece, and a Sanborn nose clip were the types of accessories used. The mouthpiece and nose clip were used invariably on adults and in about half of the tests on children. Those cases in which the mask (face inhaler) was used on children are indicated by an asterisk (*) in Table I. The quantity of oxygen consumed in

*From the Child Research Council and the Department of Biochemistry, University of Colorado School of Medicine, Denver.

A preliminary report of this study was made at the meetings of the Colorado-Wyoming Academy of Science at Golden, Colorado, in November, 1941 (Iliff, Alberta, Anna Marie Duval and Robert C. Lewis, J. Colo.-Wyo. Acad. Sci. 3: 56, 1942).

Received for publication, December 22, 1942.

a given length of time was measured, and a value of 4.825 calories per standard liter of oxygen was used to calculate the heat production. In order to determine the consumption of oxygen, check tests of four or more minutes in length were procured in all cases. If the oxygen consumption showed a deviation of more than 4 per cent from the mean when two determinations were made, at least one more test was obtained. For three or four tests to be acceptable, it was required that the oxygen consumption in each case fall within 5 or 7 per cent, respectively, of the mean of all tests.

Alcohol check determinations were made on both types of apparatus during this study. With the chamber method these determinations are made routinely about four times a year. The procedure and the results obtained are given in other publications.[1, 6] The amounts of oxygen consumed and of carbon dioxide produced by the burning of a known quantity of alcohol in the chamber have been found to fall within ±2 per cent of the theoretical values. Twenty-nine determinations with the closed circuit apparatus were made during this study by means of the alcohol check apparatus of Jones,[7] and in these the amount of oxygen consumed varied from the theoretical values by −3.1 to +3.0 per cent with an average deviation of +0.4 per cent.

EXPERIMENTAL PROCEDURE

The experimental procedure followed was to make a determination of basal metabolism in the chamber either immediately preceding or immediately following one with the closed circuit bedside apparatus. Such comparisons were made in 65 instances on 36 children (19 boys and 17 girls) between the ages of 2 years, 8 months, and 15 years, 3 months, and in 55 instances on 25 adults (8 men and 17 women). All subjects were in a postabsorptive condition when the tests were performed. The children had had a normal amount of sleep and were brought from home in an automobile by one of the workers in the metabolism laboratory. The adults had had approximately eight hours' sleep on each of the two nights preceding a test and came to the laboratory by automobile.

In the majority of experiments, a determination was made first with the chamber and then with the McKesson Metabolor. After the subject was comfortable and relaxed, the lid of the chamber was closed and, when the preliminary period (thirty minutes for children and forty-five minutes for adults) had elapsed, samples of air were collected for analysis. The lid of the chamber was then raised, and while the subject remained quiet the body temperature, the pulse rate, and the respiratory rate were taken. The determination with the McKesson Metabolor was then made.

When the bedside method was used first, it was necessary for the subject to remain quiet fifteen or twenty minutes longer than when the reverse order was followed. Since many of the children were inclined to become restless when the experimental period was thus prolonged, only four experiments in which the determinations with the closed circuit apparatus preceded that with the chamber were conducted on children. With adults, 23 experiments were made in this sequence. After the subject rested in the chamber for the preliminary period (thirty minutes for children and forty-five minutes for adults), the consumption of oxygen was measured with the McKesson Metabolor. When satisfactory determinations

had been obtained, the bedside apparatus was disconnected and the lid of the chamber was closed. After allowing a period of fifteen or twenty minutes to permit the carbon dioxide in the chamber to reach equilibrium, samples of air were collected for analysis.

EXPERIMENTAL RESULTS

The experimental results show an excellent agreement between the values obtained by the bedside method and by the chamber procedure. The calories per hour per square meter of body surface found by each of the two methods are given in Table I for children and in Table II for adults. These tables also give the difference between the values obtained by the two methods in each case in terms of percentage deviation from the determination made in the chamber. These deviations are shown graphically in the accompanying histograms (Fig. 1 for children, and Fig. 2 for adults). The results with the closed circuit bedside method show a deviation from those with the open circuit chamber procedure of from −7.5 to +6.7 per cent (mean variation = −0.2 per cent) for children and of from −8.6 to +9.3 per cent (mean variation = +0.1 per cent) for adults. The order in which the determinations were made had no effect on the results, for

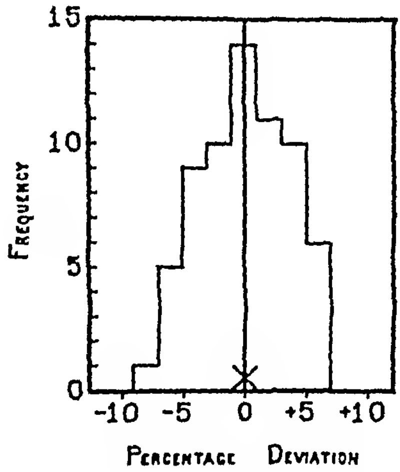
it was found that, whichever procedure was followed, the value obtained with the bedside apparatus was in some instances higher and in some lower than that procured with the chamber method. The tests in which the bedside procedure was performed first are indicated by a dagger (†) in Tables I and II.

The coefficient of correlation of the calories per hour per square meter of body surface as determined by the two methods has been calculated by the formula, $r = \dfrac{\dfrac{\Sigma xy}{n} - m_x m_y}{\sigma_x \sigma_y}$, where x represents the calories per hour per square meter as determined by the chamber method; y, the calories per hour per square meter as determined with the McKesson Metabolor; n, the number of tests; m, the mean; and σ, the standard deviation of the calories per hour per square meter. The formula, $\sigma_r = \dfrac{1 - r^2}{\sqrt{n}}$, has been used to determine the standard error of the coefficient of correlation. The value found for the coefficient of correlation of the calories per hour per square meter of body surface as determined by the two methods is 0.94 with a standard error of ±0.013 for children and 0.81 with a standard error of ±0.046 for adults. These values show an excellent correlation between the two methods both for children and for adults.

Table I shows also that reliable determinations of basal metabolism can be procured with a bedside apparatus on children under 8 years of age. This is evident, since the results of the determinations with the portable apparatus on the sixteen younger children are as satisfactory as are those on the children over 8 years old. A preliminary period of training to procure successful determinations was found necessary with three of the children between 2 and 8 years, but five of the twenty older children also required a period of training. These eight children are indicated by a double dagger (‡) in Table I. Several other investigators, who have used a mask or a mouthpiece and a nose clip, have reported satisfactory results on children under eight years old. Göttche[8] procured reliable determinations on four children and Farr[9] on seven children between 3 and 8 years of age. In the large series of de Bruin[10] there were 196

children between the ages of 1 and 8 years on whom successful observations were made. Both Farr and de Bruin reported that a preliminary period of training was frequently necessary. The results of the present study and of the other investigations cited would seem to refute the contention of Talbot, Wilson, and Worcester[11] that children of 7 years or younger cannot be tested with a portable apparatus.

The fact that satisfactory determinations of basal metabolism on children have been obtained both with the chamber procedure and with the bedside apparatus shows that factors other than the type of apparatus used determine the success to be attained when children are studied. Among these factors are those inherent in the subject on whom the determinations are being made. All workers in the field of energy metabolism realize how essential it is to obtain the cooperation of the subject to the end that he will remain quiet throughout the determinations. They will also agree that it is more difficult to secure cooperation from children, and particularly from young children, than from adults. This difficulty may be overcome, however, if the persons who conduct the test have experience with children and are patient. It is first necessary to win the child's confidence and then to enlist his help in making the determination a success. When full cooperation is procured in this way, a satisfactory determination of basal metabolism can be obtained.



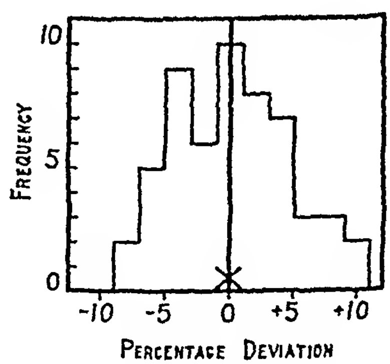


Fig. 1.—Frequency distribution of the percentage deviation of the calories per hour per square meter obtained on children with the closed circuit bedside method from those found with the open circuit chamber procedure. X represents the mean percentage deviation with regard to sign.

Fig. 2.—Frequency distribution of the percentage deviation of the calories per hour per square meter obtained on adults with the closed circuit bedside method from those found with the open circuit chamber procedure. X represents the mean percentage deviation with regard to sign.

Reference has been made in the beginning of this report to the standards of basal metabolism established by the investigations of the Child Research Council at Denver. These standards which were first published by Lewis, Kinsman, and Iliff[1] in 1937 have been slightly modified by the inclusion of data obtained since that time, and may be found with tentative standards for the fourteenth, fifteenth, and sixteenth years in a forthcoming article by Lewis, Duval, and Iliff.[12] From the results of the present study it may be concluded that these

standards for basal metabolism of children are equally reliable whether a closed circuit bedside method or a chamber procedure is used.

SUMMARY

1. Either immediately preceding or immediately following a determination of basal metabolism with an open circuit chamber method, 65 determinations on 36 children between the ages of 2 and 16 years and 55 determinations on 25 adults were made with a closed circuit bedside apparatus.

2. An excellent correlation between the results obtained by the two methods was found both for children and for adults.

3. Evidence is presented that, contrary to general belief, reliable determinations of basal metabolism on children under 8 years of age may be procured with a bedside type of apparatus.

4. The importance of obtaining cooperation from children in order to insure the successful determination of basal metabolism and the means employed to accomplish this end are discussed.

5. The standards for the basal metabolism of children established by the Child Research Council of Denver with an open circuit chamber procedure are shown to be suitable for use when the determination is made with a portable closed circuit apparatus.

LABORATORY METHODS

GENERAL

BIOPSY OF BONE MARROW PERFORMED BY A NEW AND SIMPLE INSTRUMENT*

HENRY TURKEL, M.D., DETROIT, MICH., AND
FRANK H. BETHELL, M.D., ANN ARBOR, MICH.

THE examination of marrow usually obtained from the sternum by aspiration has become an almost universal practice in the diagnosis of hemopoietic disorders, disturbances of the reticulo-endothelial system, certain infectious diseases, and primary or metastatic neoplasms within the marrow cavity. The advantages of the aspiration method lie in the ease in which the test may be performed, its relative freedom from discomfort or inconvenience to the patient, and the technical similarities between the stained films of aspirated marrow and those prepared from circulating blood. On the other hand, the aspirated material may not be representative of the quantitative relationship between cellular elements within the marrow; in myelosclerosis, no material may be obtainable; and in hypoplastic states, the information gained by aspiration is of uncertain significance. Moreover, films prepared from the mixture of marrow and blood secured by aspiration permit no conclusions regarding the anatomical relationship of the marrow elements.

The limitations of the aspiration method of sternal biopsy have led many hematologists to place chief reliance upon the examination of material obtained by trephine. A number of instruments have been derived for this purpose and that employed by Dameshek[1] is particularly satisfactory. Nevertheless, the minor surgical procedure involved, with incision and resulting scar, has precluded the general application of the method for diagnostic purposes.

It is the object of this communication to describe an instrument designed to obtain a small specimen of marrow with no more effort and actually less discomfort to the patient than are involved in the ordinary aspiration procedure. This device, with minor modifications, is also adapted to the securing of biopsy material from tumors and soft tissues. This instrument consists of two needles with stylets, an outer guiding needle of 14 gauge (*A*), and an inner trephine needle of 17 gauge (*B*), Fig. 1.

*From the Thomas Henry Simpson Memorial Institute for Medical Research, University of Michigan.

Received for publication, Sept. 4, 1942.

The external guiding needle should be 2 to 3 cm. in length. One end of this needle has a sharp beveled point, while the other end has a hollow head with a slot into which the projection of the head of the stylet fits. This arrangement keeps the point of the needle and the point of the stylet at the same cutting angle. The purpose of the guiding needle is to cut (split) through the skin and subcutaneous tissue without excising them, and to direct the inner trephine needle to the desired position.

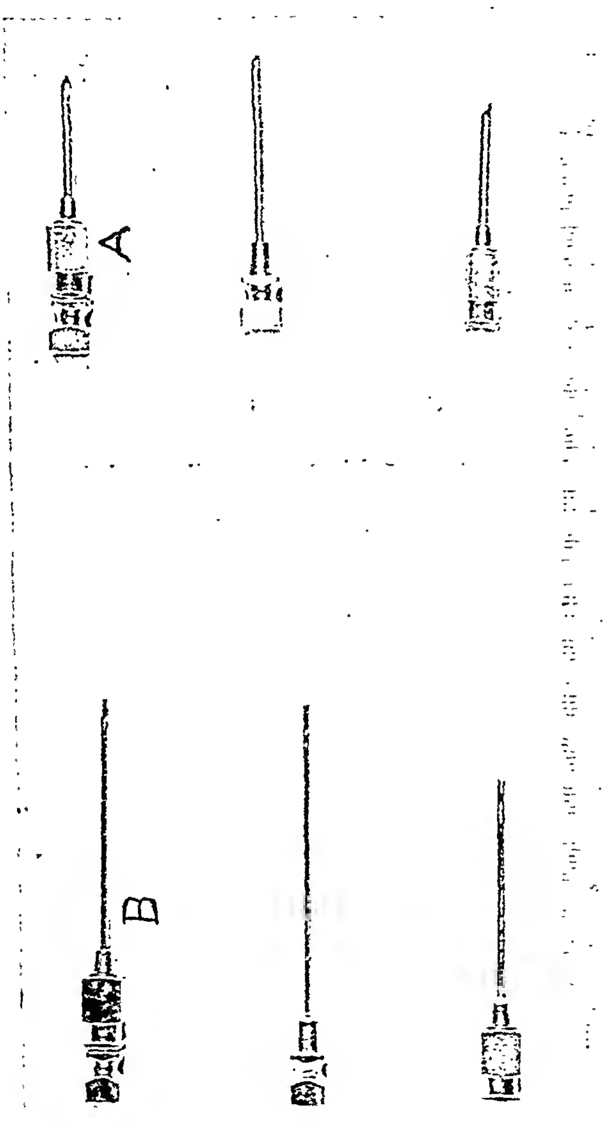

Fig. 1.—Trephine needle for bone marrow biopsy.

The internal or cutting needle, whose diameter is equal to that of the stylet of the external needle, is designed to be slipped within the external needle after the stylet is removed. The length of the two needles may be varied, but the relation must be such that the shaft of the internal needle is 5 mm. longer than the entire length of the external needle. The tip of the inner needle possesses four

saw teeth. The inside surface of the tip is cone-shaped or converging, so that the tissue becomes wedged into the needle (like a cork stopper into a flask) after being cut, and remains within the needle when the latter is removed.

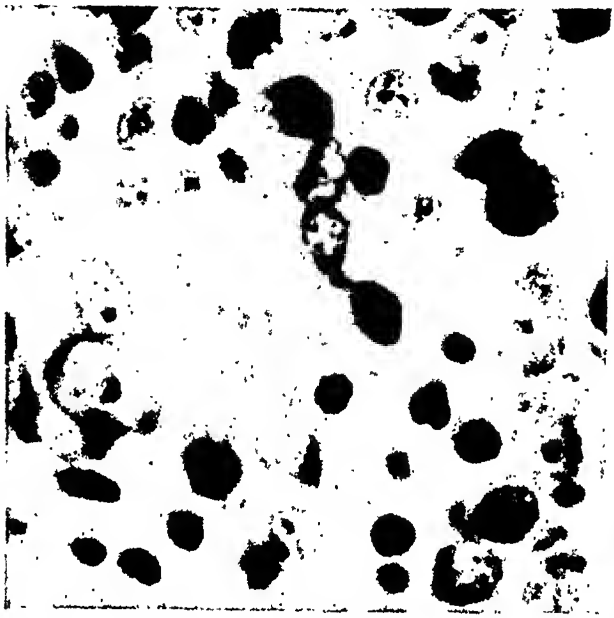

Fig. 2.—Marrow section, physician 57 years of age, suffering with subleucemic myeloblastic leucemia. No diagnostic cells were found in the blood film or aspirated material. Subsequently the disease entered a leucemic phase.

Fig. 3.—Marrow section, female 57 years of age, exhibiting nests of carcinoma cells not demonstrable by the aspiration technique. The patient was suffering with carcinoma of the breast.

The head of the internal needle is hollow, but without a slot. A standard adapter or syringe would fit into the heads of both needles. The stylet has no

projection on its head, but its stem is slightly longer than the inner needle, thus extending through the tip. This additional length serves to express the biopsy

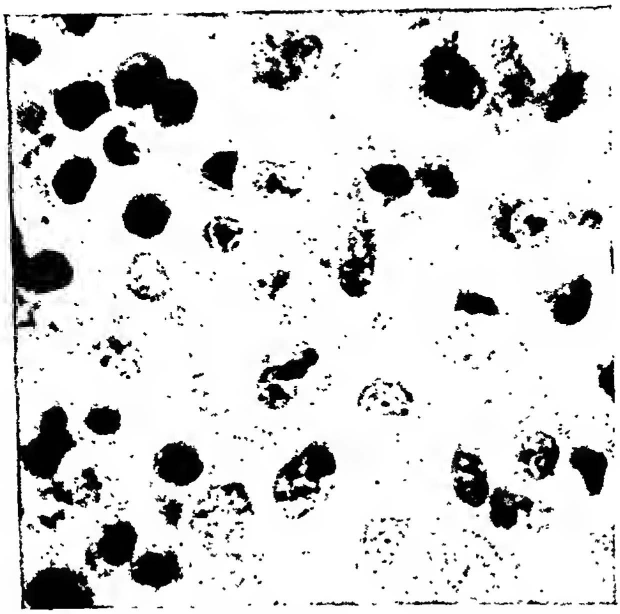

Fig. 4.—Marrow section, 44-year-old male, with multiple myeloma. Atypical plasma cells and plasmablasts were also seen in the films of aspirated marrow.

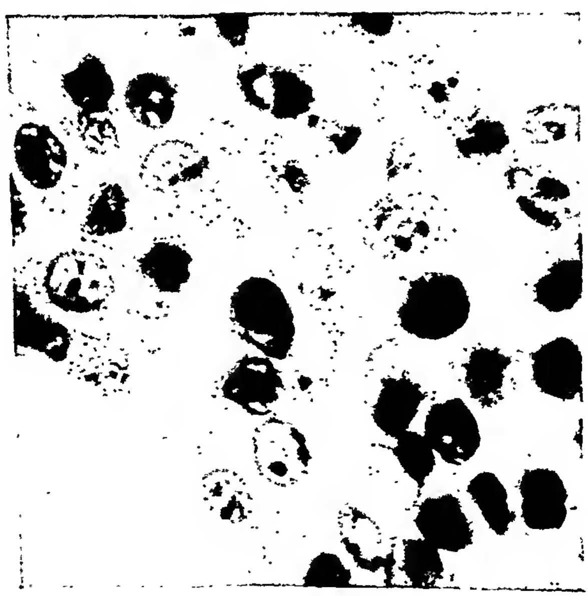

Fig. 5.—Marrow section, female 65 years of age, with subleucemic reticulosis (histiomonocytic leucemia). In this case the aspiration films were diagnostic.

material out of the inner needle and also protects the cutting tip from injury when the inner needle is inserted into the outer needle.

TECHNIQUE FOR STERNAL TISSUE BIOPSY

1. Cleanse the skin over the desired site, usually opposite the third rib, with a surgical antiseptic solution.
2. Infiltrate the skin, subcutaneous tissue, and periosteum with a local anesthetic (procaine 1.5 per cent).
3. Insert outer needle with stylet in place, with the tip of needle in direction of the face of patient at an angle of about 45 degrees, through the skin, subcutaneous tissue, and periosteum, until point just engages the anterior lamella of the sternum.
4. Remove stylet of the outer needle.
5. Insert cutting needle with stylet into outer needle.
6. Remove stylet of inner needle.
7. While holding the head of the outer needle with fingers of the left hand, turn the head of the cutting needle with fingers of the right hand backwards and forwards through a half circle, at the same time exerting gentle pressure. A sudden release of resistance signifies the entrance of the cutting tip into the sternal cavity. The cutting action with slight pressure should be continued until the needle has entered the sternal cavity for a distance of 2 to 3 mm. The needle should then be revolved several times without further insertion in order to insure detachment of the plug from the surrounding marrow.
9. Remove the inner needle.
10. Remove the outer needle.
11. Cover the point of insertion with a collodion dressing.
12. Insert stylet into the inner needle and push out the biopsy core into a bottle containing fixative solution.

It is usually also desirable to prepare films of aspirated marrow and for this purpose material obtained from the trephine hole is not, as a rule, satisfactory, because of the admixture of excessive amounts of blood. We have preferred to anesthetize a sufficiently large area to permit insertion of an aspiration needle about 1 cm. below the point of introduction of the trephine. The additional manipulation causes the patient no further discomfort, and in fact, he is usually not aware that two punctures have been made.

For fixation we have employed 100 c.c. of Zenker's solution with 5 c.c. of glacial acetic acid added just before using. After twenty-four hours, no further decalcification is required. The specimens are then washed, dehydrated, cleared, and imbedded in paraffin in the usual manner. The sections are cut with a thickness of five microns. The most satisfactory stains which we have used are Giemsa-Wolbach[2] and Kingsley.[3]

The procedure has been carried out, in conjunction with aspiration, on one hundred twelve patients representing a wide variety of hematologic conditions, and suspected primary or metastatic neoplasms of the marrow. A detailed analysis of the observations made on these patients, as well as a much larger series in which aspiration alone was done, will be published in a later communication.

Only rarely is positive diagnostic information obtained by the trephine method and not by aspiration, but such cases do occur. (Figs. 2 and 3.) The

accompanying photomicrographs were made with a 2 mm. apochromatic objective and 10× compensating ocular.

SUMMARY

1. The advantages and limitations of the aspiration method of marrow biopsy are discussed.

2. An instrument is described which enables a small specimen of marrow to be obtained by trephine without a skin incision. Photomicrographs of marrow sections secured by this method are presented.

THE NONSPECIFICITY OF THE SERUM-OPACITY TEST FOR CLOSTRIDIUM WELCHII*

LYLE A. WEED, PH.D., M.D., AND SHERMAN MINTON, JR., M.D.
INDIANAPOLIS, INDIANA

INTRODUCTION

THERE has long been a need for the rapid identification of *Clostridium welchii* in specimens taken from traumatic cases with symptoms and signs of gas gangrene. In time of war this need is much greater and the available laboratory facilities are usually fewer. It is quite natural therefore in the present emergency to attempt to utilize the reaction described by Nagler,[1] since it is supposed to be specific for the Type A toxin of *Cl. welchii.* It is the purpose of this communication to call attention to the error of using such a test, which in reality is entirely nonspecific; because other antisera will prevent the reaction, and many common aerobes ordinarily present in contaminated wounds may also give a positive reaction.

HISTORICAL

In 1939 Nagler[1] pointed out that *Clostridium welchii* grown in a mixture of human serum and broth produced opacity in the medium. Usually, but not always, a curd was formed which on centrifuging rose to the surface of the fluid, while the bacterial cells deposited on the bottom of the tube left a clear fluid intervening. This reaction could be entirely prevented by growing the organisms in a similar mixture which contained in addition *Cl. welchii* antitoxin. All strains of *Cl. welchii* tested gave the reaction, but all other anaerobes used did not. These facts suggested the reaction was specific for *Cl. welchii* and that it was probably due to Type A toxin, since all four types (A, B, C, and D of Wilsdon's classification[2]) gave the reaction.

*From the Department of Bacteriology and the Research Division, Indiana University Medical Center, Indianapolis.

Received for publication, August 15, 1942.

Recently Hayward[3] reported the use of this reaction in the rapid identification of *Clostridium welchii* in clinical material submitted for examination. She also tested 174 strains of known non-welchii anaerobes and found that 9 gave positive results or 5.1 per cent. She also found considerable variation in the amount of inoculum required to obtain a positive reaction when using known strains of *Cl. welchii*, the required number of organisms varying from as low as 400 to as high as 200,000. Whereas Nagler originally found the reactions to be positive in 16 to 18 hours' cultivation, she found some strains required as much as three days to produce opacity or coagulation. There is no evidence that she tested any of the common aerobes which would likely be present in clinical material submitted for routine bacteriologic examination. To date we have found no literature indicating any one has studied this reaction employing aerobes in place of anaerobes except the report by Nagler,[1] who used a pseudoanthrax organism.

EXPERIMENTAL

The technique described by Nagler was followed in detail except where other antiserums were used in place of *Cl. welchii* antitoxin. The tubes were incubated eighteen hours in the anaerobic jar. The controls always showed good growth and the reactions were definite.

Table I shows the production of a positive reaction with many aerobes and anaerobes other than *Cl. welchii* and the inhibition of the reaction with various types of antitoxins. It also shows the inability of *Cl. welchii* antitoxin to prevent the reaction. The data very clearly demonstrate the nonspecificity of the reaction.

CONCLUSION

The serum opacity reaction for the identification of *Cl. welchii* may be prevented by heterologous antitoxins. The reaction is produced by many common aerobes and anaerobes and these reactions may likewise be prevented by the use of nonspecific antitoxins. The reaction should not be used for the identification of *Cl. welchii.*

DOSING OF POWDERED DRUGS TO SMALL ANIMALS*

MAX STERNE
TRANSVAAL, SOUTH AFRICA

I HAVE noticed in several recent publications that workers use the stomach tube for dosing small animals with powders such as sulfapyridine. This is neither accurate nor easy, and is risky when animals are weak or ill as a result of experimental procedures.

The instrument described in Fig. 1 costs nothing. With it, small animals such as guinea pigs, rabbits, and cats can be dosed safely and expeditiously.

The end of the barrel of a broken-tipped 1-c.c. tuberculin syringe is cut off and ground flat. The outer edge is beveled slightly so as to avoid a cutting edge. A light metal sleeve, which can be cut from the guard in which large veterinary hypodermic needles are packed, is fitted over the plunger and adjusted so that ½ mm. of the plunger projects when this is pushed home into

*From the Onderstepoort Laboratories.
Received for publication, Sept. 10, 1942.

the barrel. The sleeve simply acts as a stop. An instrument without the sleeve, and with the plunger cut to the proper length, is not nearly so handy. The making takes about fifteen minutes.

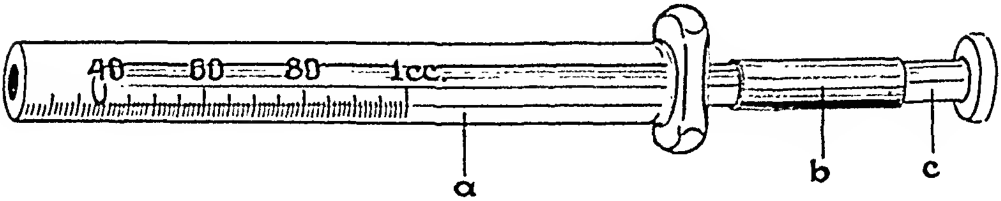

Fig. 1.—a, barrel; b, sleeve; c, plunger.

TABLE I

WEIGHTS OF TWENTY SUCCESSIVE FILLINGS

TO ADMINISTER 100 MG.	TO ADMINISTER 200 MG.
99.5	203.0
100.0	203.0
100.0	199.0
101.0	202.0
103.0	201.5
102.5	199.0
100.0	203.0
103.5	201.0
101.5	203.0
102.5	201.0

The instrument, which is merely a small balling gun, is filled by withdrawing the plunger to a mark calibrated for the required dose (one of the original gradations), and dabbing the end of the barrel into a small container of the powder until the powder reaches the end of the plunger. The end of the balling gun is pushed over the back of the animal's tongue, and the load discharged. A good degree of accuracy is obtained by this filling method. Table I gives the weights of twenty successive fillings for administering 100 and 200 mg. doses of sulfapyridine to guinea pigs.

AN IMPROVED METHOD FOR THE ISOLATION OF MANNITOL-FERMENTING SHIGELLAE*

OSCAR FELSENFELD,† M.D., MANTENO, ILL.

INDUCED by the unsatisfactory results encountered with the preserving fluids in prevalent use for Shigellae, search was instituted for more adaptable media. Among others, the fluid of Bangxang and Eliot[1] was tested for such suitability. Although announced over two years ago, this medium apparently had not obtained extensive application, and in order to ascertain its effectiveness, a test was made with laboratory strains of Shigellae, and with feces infected, in vitro, with Shigellae.

The subcultures from Bangxang and Eliot's medium inoculated in this manner proved rich in Shigellae for a period of at least four days. Because sulfa drugs may inhibit the growth of Shigellae, the fluid was tested also for its suitability in preserving Shigellae in the feces of persons treated with such drugs. The necessity to counteract sulfa drugs presented itself as an urgent task. The amount of 5 mg. p-aminobenzoic acid per 100 c.c. of the fluid was found sufficient to abolish the inhibitory effect on any microbes of sulfanilamide, sulfathiazole and sulfaguanidine when these drugs were given in the usual therapeutic concentrations. The amount of 5 mg. per 100 c.c. was chosen as a standard supplement of Bangxang and Eliot's preservative. P-aminobenzoic acid in this concentration does not stop the growth of mannitol-fermenting Shigellae.

It was found that the optimal efficacy of the preserving fluid is guaranteed at a pH around 8 and that dried bile may be substituted for sodium desoxycholate. Therefore the medium was prepared in the following modification:

Dissolve 10 Gm. of sodium citrate, 10 Gm. of peptone, 5 Gm. of sodium desoxycholate (or 6 Gm. of dried bile) and 9 Gm. of sodium chloride in 1 L. distilled water. Add 3 c.c. of a 1 per cent monosodium phosphate solution, neutralize with n/10 sodium hydroxide. Add 0.05 Gm. p-aminobenzoic acid; adjust pH to 8 with sodium hydroxide; tube, or put in containers filling up one-third of the glass. Sterilize in flowing steam.

For the diagnosis of the members of the Shigella group, plating on several media is an established routine. A variety of media was plated from the Bangxang and Eliot fluid, and the outcome evaluated.

The new plate of Wilson and Blair was used simultaneously with the plates of MacConkey; Holt, Harris, and Teague; Leifson; Endo; Wilson, Blair, Hajna and Perry; and selenite enrichment with consecutive plating on one of Leifson's plates, in the examination of proctoscopic specimens.

*From the Bacteriological Laboratory of the Manteno State Hospital, Manteno, Ill.
Received for publication, Sept. 19, 1942.
†Present address: Chicago State Hospital, Chicago, Ill.

Shortly after Wilson and Blair[2] described their new medium for the cultivation of *Shigella paradysenteriae*, it was praised by Thomas and Hulme.[3] On this plate, *Shigella paradysenteriae* grows in pink or colorless colonies. Strong lactose fermenters form a yellow growth. Escherichiae, Aerobacters, Protei, and Pseudomonades are said to be retarded.

It was found that the rosolic acid and the potassium tellurite used in the new medium of Wilson and Blair have to be standardized against known strains. The pH of the medium must be carefully observed. The alteration of the pH by the addition of the iron citrate, rosolic acid, and tellurite must be corrected to the final optimum of 7.6 to 7.8. At this pH, not only Flexner strains, but also Sonne strains grow on this medium very well. Heavy inocula may be used without courting the danger of overgrowth. While some fast growing strains of Proteus and Pseudomonas render the interpretation even of such selective plates as those of Leifson difficult, Wilson and Blair's medium is not disturbed by spreaders.

MacConkey's medium was prepared with the addition of 0.3 Gm. chloral hydrate per liter.[4] In this form, the spreading of most Proteus strains is checked. Addition of 3 c.c. of a 0.4 per cent solution of bromthymol blue per liter of medium rendered the medium more legible.

The media of Holt, Harris, and Teague, Leifson's desoxycholate plate, and Endo's medium were prepared according to the prescriptions of the American Standard Methods.[5] Leifson's desoxycholate-citrate plate was purchased on the open market. Endo's medium was omitted after it failed in 60 per cent of the first series of examinations.

Over eight hundred proctoscopic specimens were examined one to six hours after they were taken. Fifty-one specimens harbored *Shigella paradysenteriae* (Flexner). Twenty-two revealed *Shigella sonnei*, and one contained members of both groups. Many positive specimens were taken from the same individual over varying time intervals.

Twenty-five specimens gave a positive result on all four plates (desoxycholate-citrate, MacConkey, Wilson-Blair, and Teague).

Ten specimens were positive on desoxycholate-citrate, MacConkey, and Wilson-Blair medium, but negative on Teague.

Five specimens were positive on desoxycholate-citrate, Wilson-Blair, and Teague, but negative on MacConkey.

Seven specimens were positive on desoxycholate-citrate, MacConkey, and Teague, but negative on Wilson-Blair.

Two specimens were positive on MacConkey, Wilson-Blair, and Teague, but negative on desoxycholate-citrate.

Two specimens were positive only on desoxycholate-citrate and MacConkey.

Eight specimens were positive only on desoxycholate-citrate and Wilson-Blair.

Eight specimens were positive only on MacConkey and Teague.

Three specimens were positive only on desoxycholate-citrate.

One specimen was positive only on MacConkey.

Two specimens were positive only on Wilson-Blair.

One specimen was positive only on Teague.

Summarizing these results, from the seventy-four positive specimens:

Sixty were positive on the desoxycholate-citrate plate	82 per cent.
Fifty-eight were positive on MacConkey's medium	78 per cent.
Fifty-six were positive on Wilson-Blair's new plate	70 per cent.
Forty-eight were positive on Teague's medium	65 per cent.

All three forms of colonies (S, R, and G) appeared only on the plate of MacConkey, on Leifson's desoxycholate medinm, and to a smaller extent on Teague's plate. The desoxycholate-citrate medium does not permit the growth of all forms, an observation made already by Ruys.[6] Wilson and Blair's plate showed the same characteristics. The advantage of a "heavier" inoculum on selective media is therefore equilibrated by the advantage of "all colony forms growing" on nonselective plates.

Bangxang and Eliot's preserving fluid was effective in our cases when, between the taking of the specimen and the plating, some hours had elapsed.

It should be added that the procedure described revealed not only mannitol-fermenting Shigellae, but in two cases, *Eberthella typhi,* and in two other cases, *Salmonella suipestifer.*

SUMMARY

It seems that the only way to obtain a high number of positive results is to use several selective and nonselective plates simultaneously. The preserving fluid of Bangxang and Eliot is recommended. From the selective media those of Leifson, and of Wilson and Blair, from the nonselective plates those of MacConkey, and of Teague proved to be satisfactory. Wilson and Blair's new plate is not superior to other media. It is easy to prepare, it is selective, and it deserves therefore to be added to the series of routine plates.

I wish to thank Dr. H. J. Shaughnessy, Chief, Division of Laboratories, Department of Public Health, Chicago, Ill., and his assistant, Miss F. Friewer, Chief of the Typhoid Section of the Central Laboratory of the Department of Public Health, Chicago, Ill., for constant advice and helpful suggestions in this work.

A METHOD FOR THE DETERMINATION OF STAPHYLOCOCCAL ANTITOXIN AND ANTICAPSULAR AGGLUTININ USING CAPILLARY BLOOD*

JOHN A. LICHTY, JR., M.D., AND CHRIS P. KATSAMPES, M.D., ROCHESTER, N. Y.

DURING a study of staphylococcal antitoxin and anticapsular agglutinin in the blood of mothers and their infants, the difficulty of obtaining sufficiently large samples of venous blood from the infants prompted us to devise a method that would require only the small amounts of capillary blood obtainable by heel puncture. The method described herewith has proved to be highly satisfactory.

PREPARATION OF SAMPLE

Exactly 0.05 c.c. of capillary blood is drawn into a glass pipette previously rinsed with a 0.2 per cent solution of potassium oxalate in saline. The blood is introduced into a 10 mm. glass tube containing 0.45 c.c. of the oxalate solution and is shaken vigorously to avoid clotting. After centrifuging for a few minutes, 0.35 c.c. of the supernatant can be removed for the two determinations.

A. DETERMINATION OF ANTITOXIN

For titration of antitoxin, 0.25 c.c. of the supernatant is diluted in series, using 10 mm. test tubes containing 0.25 c.c. of physiologic saline (0.85 per cent NaCl). To each tube is added 0.25 c.c. of a 1:4 dilution of the staphylococcal toxin (hemolysin), as used for the routine titration of venous serum antitoxin, and the mixture is placed in a water bath at 37° C. for fifteen minutes. Finally, 0.5 c.c. of a 1 per cent suspension of fresh, thrice-washed rabbit erythrocytes is added to each tube, bringing the total volume to 1 c.c. The tubes are again placed in the water bath at 37° C. for an hour and then left in an icebox at 4° C. overnight. The following day the test mixtures are kept at room temperature for ten minutes before the presence of hemolysis is observed by gently rotating each tube in the rack. The hemoglobin always rises from the bottom of the tube before the unhemolyzed cells. In a dilution series the last tube showing no hemolysis represents the end point.

For each group of microdeterminations two controls were always used: (1) titration of a standard staphylococcal antitoxin by the routine method; (2) simultaneous titration of one subject's antitoxin by the routine, venous serum method and the micromethod. The standard antitoxin, a commercial preparation obtained from The Lederle Company, Pearl River, N. Y., was adjusted by dilution with saline so that 1 c.c. contained exactly one international unit of staphylococcal antitoxin. This preparation was stored in a sealed flask at 4° C. For the routine titration of antitoxin in venous serum, the method of

*From the Departments of Pediatrics and Bacteriology, University of Rochester School of Medicine and Dentistry and Strong Memorial and Rochester Municipal Hospitals.

Received for publication, September 24, 1942.

Parish et al.[1] was used. The staphylococcal toxin was prepared in a manner similar to that of Dolman.[2] Complete details of these two procedures are presented elsewhere.[3]

A sample group of titrations is shown in Table I. By including the titration of a standard antitoxin, the use of any convenient strength (X) of toxin is possible, and the antitoxic titer of venous serum for Subject A can readily be expressed as international units. The 1:4 (X/4) dilution of toxin used in the micromethod was obtained empirically so that the end point for this method would be at the same tube as that for the routine method. For Subject A the end point for both methods is at Tube 4. It must be emphasized that the actual amount of serum in each dilution tube of the micromethod is not the same as that for the corresponding tube of the routine method. If one can standardize the micromethod so that the values obtained by it give a constant ratio with those of the routine method, however, the amount of antitoxin present in the sample of capillary blood can be expressed in terms of international units per c.c. of serum. This is indicated in Table I by the values in parentheses.

TABLE I

SAMPLE TITRATION OF STAPHYLOCOCCAL ANTITOXIN BY ROUTINE AND MICRO-METHODS

SPECIMENS TESTED	METHOD	TITRATION TUBES 1	2	3	4	5	6	7	8	INTERNATIONAL UNITS OF ANTITOXIN/C.C. SERUM	STRENGTH OF TOXIN USED
Standard antitoxin (1 int. unit/c.c.)	Routine	O	O	O	O	O	H	H	H	1.0 (known)	X
Venous serum of Subject A	Routine	O	O	O	O	H	H	H	H	0.5	X
Capillary blood of A	Micro	O	O	O	O	H	H	H	H	(0.5)	X/4
Capillary blood of B	Micro	O	O	O	O	O	H	H	H	(1.0)	X/4
Capillary blood of C	Micro	O	O	H	H	H	H	H	H	(0.13)	X/4
Capillary blood of D	Micro	O	O	O	O	O	O	H	H	(2.0)	X/4

H = Hemolysis of rabbit R.B.C.
O = No hemolysis of rabbit R.B.C.
X = Any convenient, freshly prepared dilution of the concentrated staphylococcal toxin.
( ) = Explained in text.

The simultaneous determination of antitoxin by both methods in a group of twenty-six subjects indicates that the micromethod is well standardized and reliable. The results are compared in Table II. In twenty-two of the twenty-eight sets of simultaneous determinations, the end point by the two methods was exactly the same, and in four more the difference was only a single tube. This is within the probable error of any duplicate neutralization titration. Poor agreement of the two methods was obtained in only two instances. One seems justified, therefore, in concluding that the method of measuring staphylococcal antitoxin by using capillary blood will yield results comparable to those of the routine method requiring venous blood in most instances.

B. DETERMINATION OF STAPHYLOCOCCAL ANTICAPSULAR AGGLUTININ

The agglutination tests carried out in the present study followed essentially the method described by Lyons.[4] A hemolytic toxin-producing *Staphylococcus aureus* isolated from a case of acute osteomyelitis was used.

A shallow layer of Douglas's broth containing 0.05 per cent of glucose was inoculated with 0.1 c.c. of a twelve-hour culture of the organism for each 5 c.c.

of broth. After three hours' growth at 37° C., the culture was killed by slowly heating to 100° C., centrifuged and resuspended in saline to 1/20 of its original volume. This suspension was used in the agglutination.

For agglutinin titration 0.1 c.c. of the clear supernatant from the capillary blood sample was diluted with 0.7 c.c. of saline. Further dilutions were made in series by transferring 0.4 c.c. of the preceding dilution to 0.4 c.c. of saline in the next tube.

*These tests were performed with toxin which was six months old and it was necessary to allow the tubes to stand at room temperature for one to two hours after removing them from the icebox before satisfactory hemolysis could be observed in the micromethod.

One drop of the suspension of staphylococci was mixed with a loopful of the serum dilution on a clear glass slide. A control test of the organisms and saline was always made on the same slide. The test mixtures were gently rotated for five minutes and then read. The photographic charts of Pauli and Coburn[5] served as standards for reading the degree of agglutination.

The accuracy of the method using capillary blood in the titration of the anticapsular agglutinin was determined by the simultaneous assay of venous blood serum and capillary blood. The results of seventeen parallel determinations (Table III) showed exact agreement in eleven cases (65 per cent). In the remaining six cases (35 per cent), the variation was less than one serum dilution interval.

The values used for the micromethod in Table III are based on the assumption that the supernatant of the centrifuged capillary blood represents a 1:10

dilution of the capillary serum. This dilution is probably not 1:10, but ranges from 1:10 to 1:20, depending on the hematocrit value of the capillary blood. The results for the venous and capillary sera in Table III, however, agree more closely if the original dilution of the capillary serum is assumed to be 1:10 rather than 1:20. We have no definite explanation for this finding, but it may be due to a greater concentration of agglutinin in capillary as compared with venous serum. This notion is supported by the results obtained by calculating the ratio of staphylococcal toxin to antitoxin in the micromethod on the basis of that observed for the routine (venous serum) method. If this be done, one finds that capillary serum actually neutralizes from 2½ to 5 times the expected amount of toxin, depending on the dilution of the serum (from 1:10 to 1:20) in the sample of capillary blood. Thus, the staphylococcal antitoxin likewise appears to be more concentrated in capillary than in venous serum.

CONCLUSIONS

A method is described for the simultaneous titration of staphylococcal antitoxin and anticapsular agglutinin using 0.05 c.c. of capillary blood. A comparison of this method with the standard procedure for the titration of each antibody in venous serum shows an agreement satisfactory for serologic methods.

CHEMICAL

THE DETERMINATION OF THIAMIN IN BLOOD*

THEODORE E. FRIEDEMANN, PH.D., AND THADDEUS C. KMIECIAK, B.S.,
CHICAGO, ILL.

IT IS now generally agreed that the determination of thiamin in blood and urine is a valuable aid in the diagnosis of thiamin deficiency. Fairly accurate chemical methods have been described for the determination of thiamin in urine. It has been shown that the daily excretion of the vitamin by the kidney is related to the intake and absorption of dietary thiamin and that the determination is of considerable value, provided the subject continues his customary diet during the 24-hour period of urine collection.[1, 2] On the other hand, because of technical difficulties, chemical methods have not been successfully applied to blood. The most reliable results have been obtained by means of the cocarboxylase methods of Ochoa and Peters[3] and Goodhart and Sinclair[4, 5, 6] and the yeast fermentation method of Schultz, Atkin, and Frey.[7, 8] The first is specific for diphosphothiamin, or cocarboxylase; the second is not. Both are subject to many variations, and the techniques must therefore be carefully controlled. The fermentation method can be expected to yield higher results, since it determines the total thiamin content. The difference should be slight, however, because blood contains very little free thiamin. By using these procedures, Goodhart has shown that the whole blood of human subjects contains from 3 to 9 micrograms of total thiamin per 100 c.c. Thus, by means of the cocarboxylase method, this author found from 2.9 to 9.4, with an average of 5.4 micrograms per 100 c.c. in the blood of 50 children varying in age from 4 to 15 years.[9] The blood of 26 healthy adults contained from 3.2 to 8.7, with an average of 5.0 micrograms per 100 c.c.[4] When the fermentation method was used, the blood of 45 normal subjects contained from 3.1 to 9.2, with an average of 5.39 micrograms.[8] Our experience, in agreement with that of others, has shown that the total thiamin content of blood does not fluctuate as widely as the urinary excretion: it is not as rapidly affected by the dietary intake of thiamin. Yet a very definite correlation is noted between the concentration of total thiamin in the blood and the incidence of deficiency symptoms. Since a high percentage of subjects with polyneuropathy have blood values below 3 micrograms per 100 c.c., Goodhart has suggested that a concentration below this level indicates a state of deficiency.

The chemical procedure described by us, besides having improvements in technique, embodies many of the features described in the numerous modifications of the Jansen thiochrome method.[10-20] The principal difficulty in the analysis

*From the Department of Physiology of the Northwestern University Medical School and Passavant Memorial Hospital, Chicago.

This investigation was supported by a grant from the Abbott Fund of Northwestern University.

Received for publication, December 31, 1942.

of blood is in the precipitation of the large amount of soluble protein. This is readily accomplished by means of metaphosphoric acid, which always yields solutions which rapidly pass through the zeolite adsorbent and allow an excellent recovery of added thiamin. With a similar method, using trichloroacetic acid, Hennessy and Cerecedo[16] found from 9 to 12 micrograms per 100 c.c. of thiamin in blood. Our results, obtained by the analysis of 75 samples from 36 subjects, varied from 3.0 to 11.2, with an average of 5.70 micrograms per 100 c.c. Our data, therefore, agree substantially with those of Goodhart.

PROCEDURE

Reagents

Approximately N HCl and M $NaHCO_3$ Solutions

Metaphosphoric Acid.—A 10 per cent solution is prepared at frequent intervals, preferably each day. Since the acid deteriorates rapidly at room temperature, it should be dissolved in cold water in the refrigerator and the solution kept there when not in use.

Phosphatase.—A 10 per cent solution of taka diastase[16] or clarase[19] is prepared each day. Only the clear supernatant solution or filtrate is used.

Ion Exchange Adsorbents.—Artificial zeolites, such as Decalso,*[16] Permutit,*[18] or Crystallite† may be used. We prefer a mixture of equal parts of zeolites of 30- to 50-mesh and 50- to 80-mesh size. Columns prepared from such a mixture are not readily clogged with colloidal material and solid particles which sometimes are present in the final solution. One kilo of zeolite is covered and thoroughly mixed with 3 to 4 changes of an acidified (2 c.c. of concentrated HCl per liter) 25 per cent solution of NaCl. If ordinary table salt is used, the solution should be filtered before the addition of the acid. The supernatant solution is removed by decantation each time. The zeolite is then washed 5 or more times by decantation with acidified distilled water (1 c.c. of glacial acetic acid per liter). This washing removes the finer material as well as the excess of salt. The preparation is then transferred to a large Buchner funnel, is well washed with distilled water, and finally dried at room temperature in a shallow pan. In order to have the material in its maximum expanded state, a small portion is kept moistened in a widemouthed bottle.

NaCl Solution.—Each liter contains 250 Gm. of C.P. NaCl and 2 c.c. of concentrated HCl. Solutions prepared from table salt contain materials which slightly reduce the yield of thiochrome from thiamin. If table salt is used, the solution should be filtered before acidification with HCl.

Oxidizing Reagent.[11, 13, 18]—A mixture consisting of 9 parts of 10 N NaOH and 1 part of a 1 per cent solution of $K_3Fe(CN)_6$ is freshly prepared each day.

Iso-butyl Alcohol.[13]—The fluorescence without oxidation should be not greater than that of distilled water. Higher fluorescing batches may be used in the analysis of urine, but *they should never be used in the analysis of blood.* Should the alcohol contain much fluorescing material, it is acidified with con-

*This is obtained from the Permutit Company, New York City, New York.

†Crystallite, when prepared with the recommended very acid salt solution, does not adsorb the vitamin as well as Decalso. It may be obtained from the International Filter Company, 325 W. 25th Place, Chicago, Illinois.

centrated HCl, dehydrated with Na_2SO_4, and redistilled. Butyl alcohol may also be used.[12, 19]

The used alcohol is poured into a bottle which contains an excess of HCl. The acidified alcohol is distilled. Much water separates from the fraction which distills up to 100° C. All fractions contain water, which is removed with anhydrous Na_2SO_4 before redistillation. Calcium oxide is not used because traces of alkali in the distillate catalyze the formation of fluorescing substances.

Quinine Sulfate Standard.[20]—One hundred mg. of quinine sulfate, U.S.P., are transferred to a volumetric flask of 1 liter capacity. One hundred c.c. of approximately N H_2SO_4 are added to about 800 c.c. of solution and the volume is brought to the mark. The intermediate standard is prepared by diluting 25 c.c. of the stock standard to 100 c.c. with water and enough N H_2SO_4 to bring the final acidity to 0.1 N. The solutions are stable for at least one year if kept in the refrigerator in an amber-colored bottle. To prepare the working standard, exactly 5 c.c. of intermediate standard are diluted to 500 c.c. with water and H_2SO_4 as before. The solution should be prepared frequently. It should be protected from light and stored in the refrigerator. The fluorescence of 10 c.c. of this solution in a cuvette is approximately the same as that given by 10 c.c. of extract obtained after oxidation of 1 microgram of thiamin to thiochrome.

Thiamin Standard.—Exactly 50 mg. of anhydrous thiamin hydrochloride (dried several weeks over H_2SO_4) are dissolved in a 25 per cent solution of ethyl alcohol in approximately 0.01 N HCl. When brought to a volume of 500 c.c. with this solution, each c.c. contains 100 micrograms. This stock solution, if kept cold, is stable for at least six months. To prepare the intermediate standard, 25 c.c. of the stock solution are pipetted into a 250 c.c. volumetric flask which contains 100 c.c. of water and 25 c.c. of 0.1 N HCl. The volume is then brought to the mark. The working standard is prepared when needed by diluting 5 c.c. of the intermediate standard to a volume of 250 c.c. with 0.01 N HCl. Five c.c. contain 1 microgram of thiamin.

ANALYSIS OF WHOLE BLOOD

Collection of Sample.—Blood is collected with a syringe and prevented from clotting with a minimum of oxalate. *It is then stored in the refrigerator and the analysis is made within a few hours of collection.* These precautions are necessary, since the thiamin content changes gradually even on storage of the sample in the cold.

Digestion With Phosphatase.—Five c.c. of blood are mixed with 25 c.c. of water in a large heavy-walled test tube such as is used in the determination of nonprotein nitrogen. Two c.c. of N HCl are added, and the contents are mixed by means of a long thin footed glass rod.* The mixture is heated ten minutes with frequent stirring in a boiling water bath. It is then cooled, after which 1 drop of caprylic alcohol and 2 c.c. of M $NaHCO_3$ solution are added. The latter should be run in slowly and with stirring. This volume of solution is sufficient to bring the reaction to pH 4.5 to 5.5. 2 c.c. of phosphatase solution is now

*A J-shaped rod, with a round bend fitting the bottom of the tube is recommended. With such a rod the contents of the tube can be violently agitated by rolling the rod back and forth between the thumb and index finger. The rod should remain in the tube until the proteins have been precipitated.

added. The tube is kept 1 to 1.5 hours in a water bath at 40 to 45° C. during which time the contents are frequently mixed by stirring.*

Identical results are obtained with the following slightly modified procedure: 0.5 c.c. of *N* HCl is added to the laked blood, which is followed by incubation with 0.2 to 0.25 Gm. of phosphatase for one hour. The mixture is then further acidified with 1.5 c.c. of *N* HCl, after which it is heated ten minutes in a boiling water bath with frequent stirring, and then cooled.

A blank is prepared by adding the same reagents in the order indicated. If the alternate procedure is used, the phosphatase and 1 drop of *N* HCl are added to 25 c.c. of water. The mixture is incubated at 40 to 45° C. This blank, rather than the salt blank, is necessary to correct for the small amount of thiamin present in the phosphatase.

Precipitation of Proteins.—Ten c.c. of HPO_3 solution are next added. The volume is adjusted to the 50 c.c. mark and the contents are well mixed. The mixture is centrifugated fifteen minutes. The precipitate may contain some adsorbed thiamin which may be recovered by re-extraction. It is therefore emulsified with 2.5 c.c. of HPO_3 solution and the volume is again brought to 50 c.c.

Adsorption and Elution.—The necessary adsorption columns are prepared some time before the analysis and kept in a beaker of water until ready for use. A plug of glass wool (Pyrex No. 719) is pushed to the bottom of the Hennessy tube;† the tube is filled with water, and small quantities of moist zeolite are added until an excess, forming a layer several mm. deep, is present in the bell above the column. The adsorbent is more uniformly packed when floated into place in this manner. The excess of zeolite in the bell prevents clogging of the column by solid or colloidal material. Furthermore, it prevents access of air into the column, provided the drained column is not jarred. Just before use, water is drawn from the beaker upward through the column into the bell. The column is then placed in the rack† and allowed to drain. This assures a rapidly draining column which is free from air.

Brom phenol blue indicator is now added to the combined extracts contained in a 150 c.c. extraction flask, and the reaction is adjusted to 3.0 to 3.5 by means of *N* NaOH (or M $NaHCO_3$). The extract is then passed through the column. After passage of all of the extract, the flask is rinsed with several successive portions of about 5 c.c. each of distilled water, and the washings are sent through the column. The fluid is allowed to drain completely after each of the washings. Small portions of acidified 25 per cent NaCl solution are now added until exactly 25 c.c. of eluate have been collected in a calibrated test tube such as is used in the determination of nonprotein nitrogen.

*More or less acid, and correspondingly more or less bicarbonate solution, are necessary when tissues, feces, foods, or other materials are analyzed. The volume of acid and the length of heating in the water bath are different for each class of substance. In every case, the optimum conditions for maximum yield and recovery of added thiamin must be determined. When this is done, the procedure given by us can be applied generally to all materials. In the case of substances rich in thiamin, the contents of the tube are transferred after the digestion to a 250 c.c. volumetric flask; 15 c.c. of HPO_3 solution are added, and a suitable aliquot is analyzed as described below.

**The tube of Hennessy with the long (125mm.) stem is preferred to others which are now being sold. With the coarser mixture of zeolite recommended by us, more uniform results are obtained when the longer stemmed columns are used.

†The rack consists of a 2" x 2" board which is mounted approximately 10 inches above the table. Holes ⅝" in diameter are spaced 4 inches apart.

Melnick and Field, Hennessy and Cerecedo, and others recommend that the solution be heated and then passed through the column; the elution is carried out with hot 25 per cent solution of KCl. Heat is not necessary when a rapidly draining column, prepared as described by us, is used. *The adsorption of thiamin is equally complete from hot or cold solutions, and the vitamin is recovered just as well with cold 25 per cent solution of NaCl.*

The removal of ions by zeolites is most efficient at neutral or slightly alkaline reaction.[21] At this reaction the recovery of thiamin may be smaller than at pH 3, however, especially if the solution is heated. This is due perhaps to the sensitivity of the vitamin to alkali. For this reason the neutralization with strong NaOH must be carried out carefully.

Oxidation to Thiochrome.—Two aliquots of 10 c.c. each of the eluate are transferred to Hennessy reaction vessels of 50 c.c. capacity. Five c.c. of oxidation mixture are rapidly added, with mixing of the contents. This is followed immediately with 13 c.c. of iso-butyl alcohol. The contents are then shaken ninety seconds. Four oxidations are carried out in rapid succession. After centrifugation for a few minutes at low speed, the lower layer is drawn off, and 3 to 4 small scoopfuls (about 0.2 Gm. each) of anhydrous sodium sulfate are added. *The solvent must not be shaken with the salt, as this may produce an emulsion.* When added in this manner, the first scoopful of sulfate entraps the remaining solution at the bottom of the vessel. This is covered by successive layers of less hydrated sulfate which can then remove the water more effectively from the alcoholic phase. The extract becomes crystal-clear on standing one-half minute or so. If not clear, the mixture is very gently rotated, and 1 or 2 scoopfuls of the sulfate are added and the mixture is again centrifuged for one minute. Without further waiting, the fluorescence is then determined.

The blank is oxidized and extracted in a similar manner.

The thiamin content is obtained from a calibration curve representing the increase of fluorescence after the addition of 0.2, 0.4, 0.6, 0.8, or 1.0 microgram of thiamin to blood samples which have been analyzed by the procedure.

It will be noted that the oxidation is carried out at a considerably higher alkalinity than that used by previous workers, although a trend toward the use of larger quantities of alkali is noted in recent papers.[19, 22] More consistent results are obtained at this high alkalinity, due perhaps to the greater ionic concentration which favors the extraction of thiochrome by iso-butyl alcohol.

EXPERIMENTAL

Results of analysis of blood taken from 7 women and 29 men, a total of 36 subjects, are shown in Table I. The samples were collected from 10 to 12 in the morning and from 2 to 5 o'clock in the afternoon. They were thus taken from two to five hours after a meal. None of the samples were taken under basal conditions. These conditions were chosen because they were most convenient to the majority of subjects. They represent also the conditions under which blood is most conveniently taken from large groups of subjects in a nutritional study. In the order of numbers, the subjects consisted of research workers, students, internes, physicians, and janitors. None had received any vitamin preparations within the preceding month. All were in apparent good health, and all were receiving adequate diets. The blood of the women contained from

3.0 to 9.2, and that of the men from 3.8 to 11.2 micrograms per 100 c.c. The arithmetic mean of the results from the women was 5.60, and from the men, 5.73 micrograms per 100 c.c. The mean of all of the determinations was 5.70 micrograms per 100 c.c.

Arithmetic mean, micrograms per 100 c.c.	5.60	5.73

Diet can affect the thiamin content of the blood. The level is fairly stable on a constant diet. Thus, the blood of subject B. J. contained 6.1 micrograms per 100 c.c. at the beginning of an experiment in which the subject received a high caloric diet which contained from 1500 to 1900 micrograms of thiamin per day. The thiamin levels, determined every other day during the second and third weeks of the experiment, were 4.5, 4.3, 4.5, 5.5, 5.0, 4.5, and 4.3 micrograms per 100 c.c. On a diet containing approximately 2500 micrograms of thiamin per day, the blood of subject T. F. taken at monthly intervals contained 7.0, 9.9, and 9.9 micrograms of thiamin per 100 c.c. After two weeks, however, during which the subject received a diet containing about 300 micrograms of thiamin per day, the blood level fell to 2.8 micrograms per 100 c.c.

The following data are representative of the results which may be obtained from apparently healthy human subjects. Samples were obtained at approximately monthly intervals. The results are expressed in micrograms per 100 c.c.: K., 5.8, 6.0, and 4.9; J. H., 5.0, 5.8, and 3.9; E. A., 5.1, 8.0, and 5.1; E. G., 4.4, 7.5, 6.1, and 6.8; H., 9.2, 5.4, 3.0, and 4.1.

SUMMARY AND CONCLUSIONS

A procedure is described for the determination of thiamin in 5 c.c. of oxalated whole blood by the thiochrome method.

The blood of 36 human subjects in apparent good health and receiving an adequate diet contained from 3.0 to 11.2, with an average of 5.70 micrograms per 100 c.c. These results agree substantially with those obtained by previous workers with the cocarboxylase and fermentation methods.

A METHOD FOR DETERMINING CEREBROSPINAL FLUID PROTEIN BY THE PHOTOELECTRIC COLORIMETER*

ANDRÉ CIPRIANI, M.D., C.M., AND DORIS BROPHY, LIC. ES SC., MONTREAL, CANADA

THE estimation of the protein content of cerebrospinal fluid has become an increasingly important part of laboratory routine. The ideal method should combine accuracy with speed of operation and the use of minimal quantities of spinal fluid. The method of Denis and Ayer, as modified by Ayer, Dailey, and Fremont-Smith,[1] has proved very satisfactory, but the accuracy of the determination depends upon the ability of the technician to match turbidities in the ordinary colorimeter.

The photoelectric colorimeter has eliminated this personal factor, and turbidimetric methods would seem to be ideally suited to the instrument. Looney and Walsh[2] described such a method, using 2 c.c. of spinal fluid. Ikeda and Hanson[3] presented a similar method for further trial and evaluation. The latter method requires the use of 3 c.c. of fluid. Neither of these papers mentions the error introduced by color in some pathologic fluids.

The following method is a modification of that presented by Ayer, Dailey, and Fremont-Smith[1] for the standard colorimeter. One c.c. of fluid is used instead of the original 0.6 c.c. in order to simplify pipetting.

METHOD

One c.c. of cerebrospinal fluid is accurately measured into a test tube and 1 c.c. of 5 per cent sulphosalicylic acid is added. The tube is inverted or rotated gently to ensure thorough mixing and is allowed to stand at least five minutes before reading. The tube is then inverted again and the mixture is transferred to a small colorimeter tube after the latter has been rinsed with 2 to 3 drops of the mixture. The tube is placed in the colorimeter and the deflection is read on the galvanometer.

The center setting is determined with a tube containing 1 c.c. of distilled water and 1 c.c. of 5 per cent sulphosalicylic acid and can be used for all fluids that are clear and colorless. We have found a preliminary "warming up" period of five minutes to be sufficient for the colorimeter, provided care is taken to adjust the center setting before each reading.

All fluids which are not clear and colorless have been found to give false high results due to the added absorption of light by color. This can be compensated for by adding 1 c.c. of water to 1 c.c. of the fluid (in whatever dilution has been used for precipitation) and using this as a blank to determine the center setting. Preliminary detection of color depends upon the eye of the technician, but where there is the slightest doubt a blank reading should be made in this way. Such readings may show a deflection of as much as ten divisions

*From the Department of Neurology and Neurosurgery, McGill University, and the Montreal Neurological Institute, Montreal.

Received for publication, February 4, 1942.

on the galvanometer above the center setting (approximately 65 on a galvanometer scale divided in 100 equal parts) obtained with the water and acid blank. In contrast to this, a series of cerebrospinal fluid plus water blanks was run on 15 "clear and colorless" fluids. Fourteen of these varied only one-half of a division, and the fifteenth, three-fourths of a division, from the deflection of the water plus acid blank.

Protein concentrations from 12 to 110 mg. per 100 c.c. (17 to 76 per cent light absorption) can be estimated directly. Fluids containing higher concentrations must be diluted so that the reading falls within those limits.

APPARATUS

The apparatus consists of a miniature colorimeter of the Evelyn type[4] built to accommodate small Pyrex test tubes (8 × 75 mm.). These tubes were carefully tested for uniformity and only those conforming to the standard set by the Rubicon Company were used.

The miniature attachment for the photoelectric colorimeter is constructed as follows: Light from a 6.3 volt lamp passes through a built-in filter (Rubicon 520) and then through the solution by way of a slit 0.25 inch wide and 0.75 inch high. The test tube is so aligned that the bottom of the slit is just above the rounded portion of the tube. A removable, lightproof cap is necessary to prevent stray light from reaching the photocell via the top of the tube. The light intensity is recorded by means of a General Electric blocking layer photocell.

The instrument is included in the case of the standard Evelyn colorimeter and makes use of the same light control circuit and galvanometer. A suitable switch allows the convenient use of either instrument.

CALIBRATION

A standard protein solution was prepared according to the method of Ayer, Dailey, and Fremont-Smith.[1] Dilutions were made to give eleven standard solutions ranging in concentration from 12 to 110 mg. per 100 c.c. The protein content of each was determined in duplicate by the micro-Kjeldahl method and also the light absorption of each, after precipitation with sulphosalicylic acid, was measured in the photoelectric colorimeter. Using the actual readings on the galvanometer scale as ordinate and the concentration of protein (as determined by micro-Kjeldahl) as abscissa, points were established on graph paper and a curve drawn. This curve has been used to estimate the protein in all fluids of unknown concentration.

Duplicate determinations of protein were made on numerous samples of cerebrospinal fluid both by the photoelectric method and by micro-Kjeldahl. As noted by Ayer, Dailey, and Fremont-Smith,[1] difficulty was encountered in obtaining satisfactory checks with the micro-Kjeldahl when the nonprotein nitrogen was subtracted from the total nitrogen and the result multiplied by the factor 6.25. More consistent results were obtained by precipitating the protein with trichloracetic acid and determining the nitrogen content of the precipitate directly. This method has been compared with the direct gravimetric method by Guillaumin et al.[5] and has been found to check closely with it. It has the added advantage of requiring only two micro-Kjeldahl determinations instead of four for duplicate estimations.

RESULTS

All the figures obtained in the course of the experiment are presented in Tables I and II. It will be noted that the results of photoelectric determinations are in more close agreement with the micro-Kjeldahl results in Table II (protein nitrogen) than is the case in Table I (total nitrogen minus nonprotein nitrogen). Duplicate figures in the photoelectric method are remarkably consistent, and where the figures by micro-Kjeldahl determination were not in such close agreement the photoelectric results will be found to check fairly closely with one or the other of them. In only two instances (the second and the fourteenth) in Table II were the duplicate values for each method in close agreement while showing a distinct difference between the two methods. In one of these the

figures by photoelectric method were higher, and in the other they were lower than the Micro-Kjeldahl results.

The method is convenient and inexpensive. A single determination requires about ten minutes and even less time per determination if a number of samples are to be tested.

SUMMARY

1. A simple method is presented for the determination of cerebrospinal fluid protein with the photoelectric colorimeter.

2. A miniature attachment for the Evelyn photoelectric colorimeter is described which will accommodate small Pyrex test tubes. This permits the determination to be carried out on 1 c.c. of spinal fluid.

3. False high results may be obtained with colored specimens of spinal fluid. A method to rule out this source of error is described.

DETERMINATION OF MANDELIC ACID IN URINE*

Precipitation as Cadmium Mandelate

J. H. Phillips, A.B., V. H. Wallingford, Ph.D., and A. Q. Butler, Ph.D.
St. Louis, Mo.

MANDELIC acid and salts of mandelic acid are employed in the treatment of urinary infections and after their administration the physician may find it desirable to follow the concentration of mandelic acid in the urine of the patient. In a clinical investigation[2] on the injection of solutions of sodium mandelate this laboratory was requested to supply the analytical data. The available analytical procedures for the determination of mandelic acid in urine were studied and found to be unreliable. A new gravimetric method was developed in which the mandelic acid in the urine is extracted with ether, converted to the sodium salt for extraction and concentration in an aqueous solution, and precipitated and weighed as cadmium mandelate. The method may be carried out

*From the Mallinckrodt Chemical Works, St. Louis.
Received for publication, March 1, 1943.

fairly rapidly on a semimicro scale with 10 c.c. samples of urine, or it may be applied as a macro procedure with 100 c.c. samples. The concentration range of 0.1 to 2.0 Gm. of mandelic acid in 100 c.c. of sample was studied since this represents the normal range of concentrations encountered during mandelic acid therapy.

In 1909 Neubauer[5] determined the mandelic acid excreted by dogs after feeding experiments. The acid was extracted from the urine by ether and, after purification, was titrated with 0.1N alkali. Rosenheim,[11] who introduced mandelic acid therapy in 1935, determined mandelic acid in the urine of his patients by extracting with ether after acidifying the specimen with phosphoric acid and saturating with ammonium sulfate. The residue obtained by evaporating the ether was weighed as mandelic acid. McMahon[6] combined the Rosenheim extraction method with the titration method used by Neubauer. Montenbruck,[7] and also Garry and Smith,[3] determined the extracted *d* or *l* mandelic acid polarimetrically. This method is not applicable in human cases, however, since the inactive *dl* mandelic acid is usually administered, and it has been shown[7] that both forms of mandelic acid are excreted simultaneously. For the assay of medicinal preparations, Stevens and Hughes,[12] and also Rosen,[10] employed continuous extraction with ether followed by titration with standard alkali. Underwood[13] recommended extraction with a mixture of two parts chloroform and one part ether, followed by titration with standard alkali.

The published methods are subject to several errors. Reimers[9] indicated that care must be taken in evaporating the ether from the extract in order to avoid loss of mandelic acid by volatilization. McMahon reported the loss of an average of 6 per cent of mandelic acid in recovery experiments from water with samples ranging from 0.5 to 4.5 Gm., and 16 per cent loss in recovery from urine with samples ranging from 0.2 to 0.3 Gm. The loss was attributed to combination with other constituents of the urine. Berger,[1] using McMahon's method, reported a loss of about 10 per cent from 0.1 gram samples in recovery of mandelic acid from urine "through the combination with other urinary constituents or through inaccuracy of the method." He also reported a loss of 20 per cent in the recovery of mandelic acid added to breast milk.

DEVELOPMENT OF GRAVIMETRIC METHOD

A study of the methods reviewed above indicated a need for a more satisfactory procedure for the determination of mandelic acid in urine. In attempting to apply Rosenheim's method of extraction from 100 c.c. portions of urine, intractable emulsions were frequently encountered, but the use of the continuous method of extraction with ether recommended by Stevens and Hughes entirely overcame this difficulty. It was found necessary to acidify the urine rather strongly to insure the complete liberation of the mandelic acid. High acidity has been shown[4] to decrease the solubility of mandelic acid in water and would be expected to facilitate its extraction by ether. The extracted mandelic acid, however, was always found to be impure, and direct titration generally gave results which were high. It was found that pure mandelic acid can be nearly quantitatively precipitated by adding concentrated hydrochloric acid or

by saturating the solution with sodium chloride, but mandelic acid recovered from urine under these conditions crystallized only slowly and incompletely, presumably on account of the inhibiting action of the accompanying impurities.

Mandelic acid extracted from urine by means of ether was found to be promptly and quantitatively precipitated as the cadmium salt from aqueous solution, furnishing the basis for a satisfactory gravimetric method. McKenzie[5] prepared cadmium mandelate and listed its solubility as 0.1 Gm. in 100 c.c. of water at 16° C. Since McKenzie did not publish his analytical data, the present authors have determined the composition of cadmium mandelate precipitated under various conditions and have redetermined its solubility.

It was noted that the physical characteristics of the crystalline cadmium mandelate formed at room temperature changed appreciably when the solution with precipitate was heated on the steam bath. The cadmium mandelate was formed first as a dense crystalline precipitate which upon heating changed to a flocculent form. Pure cadmium mandelate is white, but when precipitated from urine it may be slightly colored. It was subsequently established that both forms of precipitate had the same composition after they were dried. Samples representing each of the two forms of precipitate were prepared and analyzed. Cadmium mandelate was precipitated by adding an excess of cadmium chloride solution (50 Gm. cadmium chloride in 100 c.c. water) to a slightly acidified aqueous solution of sodium mandelate, the conditions adopted for the analytical procedure described later. In one case the cadmium mandelate was precipitated at room temperature, after which it was heated on the steam bath until the physical change in the crystalline structure was noted. The precipitate was collected on a sintered glass funnel and washed with small portions of distilled water until free from chloride (Sample No. 1). A second sample of cadmium mandelate was prepared by precipitation from a previously cooled solution of sodium mandelate, and the solution and crystals were kept in an ice bath until the washing of the precipitate was completed (Sample No. 2). The two samples were dried in a vacuum desiccator and analyzed by simultaneous microcombustion for cadmium, carbon, and hydrogen. Cadmium was converted to the oxide during the course of the carbon and hydrogen combustion, and the percentage of cadmium was calculated from the residue of cadmium oxide remaining in the platinum boat. A complete combustion of the cadmium mandelate was easily obtained at a temperature well below the decomposition temperature of cadmium oxide, 900 to 1000° C. During the combustion the boat was not heated above a dull red heat. The results are shown in Table I. The values obtained for percentage composition indicated that $Cd(C_8H_7O_3)_2$ is the correct formula for both forms of precipitate. It is probable that the differences in physical characteristics are associated with hydrate formation.

Solubility determinations were made using portions of the purified cadmium mandelate samples described above, at 25° C., in water and in dilute acetic acid (the conditions recommended in the analytical procedure). Approximately 0.2 Gm. of cadmium mandelate was placed in a 200 c.c. Kjeldahl flask together with 100 c.c. of distilled water. The flask was fitted with a motor-driven glass stirrer and clamped in a constant temperature water bath. The contents of the flask were stirred slowly for three hours, at which time a sample of 15 c.c. was with-

drawn through a sintered glass filter stick into a calibrated pipette and transferred to a previously tared micro-evaporating dish. The water was cautiously evaporated on a steam bath, the dish and residue dried in a vacuum desiccator over phosphorus pentoxide and again weighed. The increase in weight was calculated to grams of cadmium mandelate per 100 c.c. of solution. A second portion was withdrawn three hours later to determine whether the equilibrium point had been attained. As a check on the results, a determination was made in which the original mixture was heated to 100° C. and then cooled to 25° C. Another determination was made in an acetic acid solution pH 4.11. The results of these determinations are shown in Table II. The average value for solubility, 0.08 Gm. in 100 c.c. of solution, is slightly lower than the value reported by McKenzie. The solubility was found to be only slightly greater in acetic acid than in water.

SOLUBILITY OF CADMIUM MANDELATE AT 25° C.

	PURIFIED CADMIUM MANDELATE SAMPLE USED FOR TEST	SOLUBILITY IN GRAMS PER 100 C.C. OF SOLUTION
Solution in distilled water adjusted to 25° C. from room temperature	No. 1	0.079
	No. 2	0.079
Solution in distilled water heated to 100° C and cooled to 25° C.	No. 2	0.078
Solution in acetic acid, pH 4.11, adjusted to 25° C. from room temperature	No. 1	0.089

The most convenient method of extraction for small samples of urine was found to be repeated shaking of the sample with ether in a 50 c.c. separatory funnel. Several solvents and mixtures of solvents, such as ether, chloroform, normal butyl alcohol, normal amyl alcohol, benzene, and carbon tetrachloride, were tried, but alcohol-free ether was found to be the best. When extracting with ether it was found necessary to avoid the use of grease on the stopcock of the separatory funnel, but the stopcock may be moistened with distilled water before the sample is introduced. Two satisfactory procedures were developed for transferring the extracted mandelic acid to a water solution preparatory to precipitation as the cadmium salt. In the semimicro procedure, the ether extract was neutralized with sodium hydroxide and the ether evaporated from the mixture. In the macro procedure, it was found expedient to extract the ether

solution with dilute sodium hydroxide and expel dissolved ether from the sodium hydroxide fraction by warming on the steam bath. By converting the mandelic acid to the sodium salt before evaporating the ether in both procedures all possibility of loss of the acid by volatilization was eliminated.

In order to avoid extracting unnecessary amounts of impurities from the urine samples by repeated shaking in the 50 c.c. separatory funnel, a series of extractions was made on 10 c.c. aliquot portions of a solution containing a known amount of mandelic acid. The results showing per cent recovery in these experiments are presented in Table III. It was found that five extractions are adequate.

TABLE III

ETHER EXTRACTION OF MANDELIC ACID FROM WATER
(0.2000 GM. MANDELIC ACID DISSOLVED IN 10 C.C. WATER)

NUMBER OF ETHER EXTRACTION	WEIGHT MANDELIC ACID RECOVERED GRAMS	RECOVERY PER CENT
3 × 30 c.c.	0.1768	88.4
5 × 30 c.c.	0.1989	99.5
7 × 30 c.c.	0.1998	99.9

METHOD OF ANALYSIS BY THE SEMIMICRO PROCEDURE

Reagents.—All chemicals used are Mallinckrodt reagents of the grade specified: Sulfuric acid A.R., diluted 1:1 by volume with distilled water; cadmium chloride solution, 50 Gm. cadmium chloride anhydrous A.R. in 100 c.c. water; sodium hydroxide 1N; chlorphenol red indicator, 0.1 per cent in 95 per cent ethyl alcohol; acetic acid glacial A.R.; ether anhydrous A.R.

Procedure.—Measure a 10 c.c. portion of the urine specimen into a 50 c.c. separatory funnel, add 1 c.c. of sulfuric acid (1:1), 30 c.c. anhydrous ether, and shake vigorously for three minutes. Allow the two layers to separate and withdraw the lower aqueous layer into a second 50 c.c. separatory funnel. Use necessary precautions to transfer all of the aqueous layer and ether-water suspension that does not separate readily. Wash the final drops from the stem into the second funnel with a stream of ether from a wash bottle. Transfer the ether layer remaining in the funnel into a 50 c.c. beaker; add 3 c.c. water, 5 drops chlorphenol red indicator, and a slight excess of 1N sodium hydroxide; and place on the steam bath with a current of air directed into the beaker. Allow all of the ether to evaporate thus leaving the mandelic acid in the aqueous layer as the sodium salt. While this first ether layer is evaporating, extract the aqueous solution in the second separatory funnel with another 30 c.c. of anhydrous ether and transfer this extract to the beaker in which the first extract was evaporated. Repeat the extraction and evaporation of the ether layer until five extractions have been made. The aqueous solution of mandelic acid in the beaker must be kept alkaline during these operations by the addition of sodium hydroxide, 0.5 to 1 c.c. at a time, as indicated by the chlorphenol red. Evaporate the aqueous solution of sodium mandelate thus obtained to about 3 c.c. and transfer quantitatively to a 10 c.c. micro beaker which has been previously weighed with a sintered Pyrex or porcelain filter stick.

Again evaporate the combined solution and washings on the steam bath to a volume of about 3 c.c., adjust the pH to approximately 5 by the addition of glacial acetic acid dropwise until the yellow color of the chlorphenol red indicator starts to appear, and finally add 0.4 c.c. of cadmium chloride solution. Evaporate the contents of the beaker to dryness on the steam bath, take up the residue in 3 c.c. of water, and allow the beaker and contents to stand for about thirty minutes with occasional agitation to obtain solution of the water-soluble salts. Filter the solution through the previously weighed filter stick. Rinse the inside of the beaker and filter stick with two 0.5 to 1.0 c.c. portions of water with successive withdrawal of each through the filter stick to remove all traces of soluble cadmium and sodium salts. Dry the beaker and filter stick in a vacuum desiccator over phosphorus pentoxide and weigh. Multiply the weight of cadmium mandelate by 0.7338 to convert to mandelic acid.

METHOD OF ANALYSIS BY THE MACRO PROCEDURE

Reagents.—The reagents are the same as those listed above for the semimicro method.

Procedure.—Any of the commonly used types of apparatus for continuous extraction by an immiscible liquid should suffice for this extraction. The type used here consisted of a 500 c.c. round bottom flask for a boiler, a 125 c.c. distillation flask for holding the sample, and a reflux condenser. Connections were made so that the condensed ether passed through a tube to the bottom of the flask holding the sample, overflowing through the side arm back to the boiling flask. The tube which returned the ether extended below the surface of the liquid in the boiler flask.

Introduce a 100 c.c. portion of the urine specimen and 10 c.c. sulfuric acid (1:1) into the distillation flask. Introduce 300 c.c. of anhydrous ether into the round-bottom flask. Connect the refluxing tube and the condenser to the two flasks, and connect the side arm of the distillation flask to the return tube so that excess ether will drain back into the round-bottom flask. Place the round-bottom flask on a steam bath or electric hot plate and allow the extraction to proceed for twelve hours, or overnight if convenient. At the end of the refluxing period, remove the round-bottom flask from the extraction setup, add 5 or 6 drops of chlorphenol red indicator and sufficient 1N sodium hydroxide to maintain the pink end-point of the indicator. Stopper the flask with a rubber stopper and shake vigorously for two or three minutes to insure that the end point has been reached. Place the round-bottom flask and contents on a steam bath and allow about one-half of the ether to evaporate. Transfer the ether-water mixture quantitatively to a 250 c.c. separatory funnel and add sufficient water to bring the total volume of the aqueous layer to 15 c.c. Shake the mixture vigorously for three minutes. Add more alkali, if necessary, to keep the aqueous layer alkaline. Withdraw the aqueous layer into a 250 c.c. beaker and rinse any adhering drops on the tip of the separatory funnel into the beaker with a stream of ether from the wash bottle. Repeat the extraction of the ether layer in the separatory funnel three more times, using 1 c.c. of 1N sodium hydroxide and 4 c.c. of water. Transfer each water extract to the same beaker. Place the

beaker on a steam bath and allow the ether to evaporate completely from the aqueous layer.

Adjust the pH of the water-extract to approximately 5 or 6 by the addition of sufficient glacial acetic acid to just reach the yellow end point of the chlorphenol red indicator. Precipitate the mandelic acid by adding 4 c.c. of cadmium chloride solution. Place the beaker containing the precipitate on a steam bath and allow the solution to evaporate to dryness. Add 10 c.c. of water to the residue, mix thoroughly, and allow to stand at room temperature for thirty minutes with occasional stirring. Filter the solution into a weighed sintered glass funnel, transferring the precipitate quantitatively into the funnel. Wash the precipitate with three 1 to 2 c.c. portions of water. Dry the funnel in a vacuum desiccator over phosphorus pentoxide and weigh. Multiply the weight of cadmium mandelate by 0.7338 to convert to mandelic acid.

DISCUSSION

The mandelic acid content of urine may be determined by either of the two procedures described above. In Tables IV and V are shown the results of experiments in which known quantities of mandelic acid were added to water and urine respectively and then recovered by the semimicro procedure. In Table VI are shown the results of experiments in which known quantities of mandelic acid were added to urine and recovered by the macro procedure. Although the methods appear to give equally satisfactory results over the range of concentrations studied, the semimicro method has the advantage that it requires considerably less elapsed time per analysis. It was found that five or six samples may be completed by the semimicroprocedure by an analyst in an eight-hour day. Another distinct advantage of the semimicromethod is that it permits the use of a smaller sample.

There is always an unavoidable uncertainty connected with the extraction of urine samples due to the lack of uniformity in the composition of different samples. It is conceivable that the cadmium mandelate procedure might be influenced by constituents in the urine, but significant interference by constituents of either normal or pathologic urine seems unlikely. A number of samples of urine originating from patients before the initiation of mandelic acid therapy were analyzed by the cadmium mandelate precipitation method, and in every case the complete absence of mandelic acid and all interfering impurities was indicated. Oxalic acid forms an insoluble cadmium salt, but it exists in urine in traces only. Hippuric acid is also only a minor constituent of human urine. The cadmium salts of benzoic acid and the common aliphatic acids are sufficiently soluble to avoid interference. Beta-hydroxybutyric acid, which may be present in urine under certain conditions, failed to yield a precipitate with cadmium chloride.

The results obtained by the cadmium mandelate precipitation method are subject to a slight error due to the solubility of the cadmium mandelate, but a high degree of accuracy is not required in a urinalysis and the solubility error is probably not significant except in samples where the mandelic acid concentration is very low. If an analysis required a more accurate determination the solubility error could be corrected either by calculation or manipulation.

*Same urine samples as reported in Table V.

From about one hundred and thirty analyses for mandelic acid in urine by the semimicro method performed in the course of a clinical investigation[2] only two specimens formed emulsions that could not be separated. Upon inquiring about the history of the specimens it was learned that they had originated from patients who had been given mercury therapy along with the sodium mandelate, which may have been responsible for the production of an emulsifying substance in the urine. These two specimens were easily extracted by a semimicro adaptation of the continuous extractor described in the procedure for the macro method. A 100 c.c. round-bottom flask and a 50 c.c. distilling flask were used in the setup. Recovery experiments on known quantities of mandelic acid added to normal urine established the fact that four to five hours was sufficient time for the continuous extraction of 10 c.c. samples.

In Table VII is shown a series of results on case specimens of urine in which the samples were analyzed for mandelic acid by both the semimicro and macro procedures.

The isolation and determination of mandelic acid as cadmium mandelate may be of value in the analysis of other solutions or mixtures such as elixirs or tablets.

SUMMARY

A method for the determination of mandelic acid in urine is presented and its use for other types of samples is suggested. The procedure is based on the extraction of the acid with ether, conversion to the sodium salt, and precipitation as cadmium mandelate. A semimicro and a macro procedure are given and two methods of extraction are described. The methods are accurate and require no special equipment or reagents. Several determinations may be carried out simultaneously.

The composition of cadmium mandelate has been confirmed by analysis and its solubility redetermined. A method is reported for the determination of cadmium as the oxide simultaneously with the determination of carbon and hydrogen by combustion.

The authors wish to express their thanks to Drs. Grayson Carroll and Reese Coleman for the privilege of collaborating with them on this investigation and to Allen G. King, librarian at the Mallinckrodt Chemical Works, for his assistance in searching the literature.

A RAPID AND SIMPLE TECHNIQUE FOR THE DETERMINATION OF GELATIN*

MARTHA JANOTA, M.S., CHICAGO, ILL.

THIS report deals with a technique for the determination of gelatin protein in a mixture of blood and gelatin or urine and gelatin in vivo as well as in vitro. The technique described here is merely the application of well-known methods and principles of chemistry in the separation of plasma and gelatin or urine and gelatin proteins. The present paper is reported because of the increased interest in gelatin as a blood substitute and because of the absence in the literature of suitable simple methods for the determination of gelatin.[1]

The basis for the separation of gelatin from plasma proteins is the property of gelatin protein in 95 per cent ethyl alcohol and in 5 per cent trichloracetic acid. (Gelatin throughout this paper refers to an autoclaved solution.) The addition of 95 per cent alcohol to a gelatin solution results in the protein of the gelatin being precipitated, the nonprotein constituents remaining in the supernatant fluid after centrifugation. The addition of 5 per cent trichloracetic acid to a gelatin solution does not precipitate the gelatin proteins. It is a well-known fact that 5 per cent trichloracetic acid or 95 per cent alcohol precipitates the proteins of serum or plasma, the nonprotein constituents remaining in solution.[2] Thus in a mixture of gelatin and plasma, the gelatin may be separated from the plasma by the precipitation of plasma proteins with trichloracetic acid, thereby leaving the nonprotein constituents of both plasma and gelatin and the gelatin protein in the supernatant fluid. Every sample of gelatin had a nonprotein nitrogen content varying between 30 and 75 mg. per cent after autoclaving. Prolonged autoclaving increased the nonprotein nitrogen and decreased the viscosity of the solution. A standardized procedure of autoclaving was used therefore. Now, if a total nitrogen determination is made by the micro-Kjeldahl method on the 5 per cent trichloracetic supernatant fluid and the nonprotein nitrogen is determined by the usual nesslerization method on an alcoholic filtrate of a plasma-gelatin mixture, the protein nitrogen of gelatin may be obtained by subtracting the nonprotein nitrogen from the total nitrogen. The protein nitrogen multiplied by the protein factor for gelatin of 5.25 yields the protein gelatin in the mixture.

The plasma protein of the mixture may be obtained by analyzing the gelatin-plasma mixture for total nitrogen, and then subtracting the total nitrogen of the 5 per cent trichloracetic acid supernatant which contains the gelatin protein nitrogen and the nonprotein nitrogen constituents of both gelatin and plasma. This figure represents total plasma protein nitrogen, which multiplied by the usual protein factor of 6.25 yields the protein of the plasma. It is obvious that

Received for publication, March 24, 1942.

by adding the plasma protein to the gelatin protein the true combined total protein of the gelatin-plasma mixture is obtained.

These same principles may be applied to gelatin-urine analysis. In passing, it should be pointed out that the qualitative tests for protein in urine, such as 5 per cent acetic acid and sulphosalicylic acid, are not suitable for the detection of gelatin, since gelatin is not precipitated by either of these reagents.

EXPERIMENTAL

Ossein or pigskin gelatins prepared in 0.85 per cent NaCl solutions, autoclaved for one-half hour to one hour at 256° F., were used in vitro and in vivo experiments. In vitro experiments were performed by mixing gelatin and plasma in varying amounts. Total proteins were determined on the gelatin and plasma before the mixtures were made; the mixtures were analyzed for gelatin and plasma proteins, and the theoretical values were calculated. In Table I are represented the theoretical and recovered gelatin and plasma protein values.

Total nitrogen determinations were made by diluting 0.5 c.c. of the plasma-gelatin mixture to 25 c.c. with 0.9 per cent NaCl and analyzing 1 c.c. aliquots for total nitrogen by the micro-Kjeldahl method of Ma.[3]

Gelatin nitrogen was determined by precipitating the plasma proteins contained in 0.5 c.c. of the gelatin-plasma mixture with 7 c.c. of 5 per cent trichloracetic acid and by analyzing 1 c.c. portions of the supernatant for total nitrogen (G.N.) by the micro-Kjeldahl method.

Nonprotein nitrogen (N.P.N.) was determined by precipitating the gelatin and plasma proteins in 0.5 c.c. of the mixture with 7 c.c. of 95 per cent alcohol, determining the amount of N.P.N. in 5 c.c. of the supernatant by the usual methods using direct nesslerization.[4]

Protein values were obtained by the following formulas:

(T.N. – G.N.) $\times$ 6.25 = Plasma protein in grams per 100 c.c.

(G.N. – N.P.N.) $\times$ 5.25 = Gelatin protein in grams per 100 c.c.

Gelatin protein plus plasma protein = Combined protein of mixture.

In vivo experiments were performed on dogs infused with known quantities of gelatin. Gelatin and plasma protein analyses on the blood of these animals one hour, twenty-four hours, forty-eight hours, seventy-two hours, and five days later indicated that gelatin left the circulation very rapidly.[5] The analyses were made in duplicate and the values obtained agreed within ± 3 per cent error.

In order to rule out the rapid loss of gelatin from the circulation due to diffusion of gelatin into the red cells, heparinized blood was mixed with equal amounts of gelatin solution. The mixture was gently shaken for one hour, and then centrifuged, with the plasma analyzed for gelatin and plasma protein. In one experiment the red blood cells of the mixtures were repeatedly washed with 0.85 per cent NaCl; the washed cells were then frozen rapidly in carbon dioxide snow and alcohol, thawed rapidly, and analyzed for gelatin. Table II represents the results of this experiment. The theoretical values were calculated from hematocrit determinations of the blood before adding the gelatin.

DISCUSSION

From the data presented in Tables I and II, it would appear that the technique for the determination of gelatin and plasma protein in a mixture of gelatin

*Analysis of washed, hemolyzed red blood cells was negative for gelatin.

and plasma is adequate for biologic purposes, the differences between the expected and the obtained values being within the limits of error of the method. Due to the viscous nature of gelatin, difficulty is encountered in adequately draining pipettes when measuring gelatin. This may in part explain the loss of gelatin in the recovery experiments, since the pipettes containing plasma and gelatin cannot be rinsed out with trichloracetic acid. When blood and gelatin were mixed, the gelatin recovery was 91.7 and 86.2 per cent. Analysis of saline washed blood cells hemolyzed on freezing and thawing (86.2 per cent recovery experiment) was negative for gelatin. These data would indicate that no, or at most insignificant, amounts of gelatin entered the red blood cells.

After the writing of this paper the work of Little and Wells appeared.[6] These authors employed sodium tungstate as gelatin precipitant and 10 per cent trichloroacetic acid as plasma protein precipitant. No recovery data were supplied.

SUMMARY

1. A technique applying known methods has been described for the determination of gelatin in a mixture of gelatin and plasma.

2. Recovery experiments indicate the method suitable for biologic purposes.

3. The technique described is also applicable to urine and gelatin analysis.

MEDICAL ILLUSTRATION

THE CONTROL OF EXPANSION AND CONTRACTION OF RUBBER CASTS*

CARL DAME CLARKE, AND FREDERICK MATTHEW STINER, WASHINGTON, D. C.

SHRINKAGE of rubber prostheses of facial and body members has presented a definite problem. Rubber shrinks slightly on setting (coagulation) and drying. This shrinkage may be great or infinitesimal. Nevertheless, it may be sufficient to cause an improper fit of the artificial part to the human tissues. Therefore the following experiments were carried out in an effort to overcome this difficulty. It was found possible to expand a rubber cast to more than three times its original surface area or slightly less than two diameters by soaking it in benzine. Likewise, it was discovered how to reduce or shrink it to a fraction of its original size. The ability to reduce the size has its place in art and medicine as well as the need for enlarging to offset shrinkage. A practical example of where shrinkage may be a necessity rather than a fault is when a rubber hand is to be made of a proper size to fit a particular individual who has lost his hand. These hands are invariably molded from a second individual (donor) for supplying a cast to the first (recipient).

Both expansion and contraction must take place without an appreciable loss of detail. Therefore, coins having a wealth of detail were chosen for these experiments. Indeed, the microscopic writing on one coin (Figs. 1 and 2) became plainly visible to the unaided eye on enlarging. It was found that in the expansion of a prosthesis the distortion often took place in proportion to the thickness of the rubber. The thinner parts became distorted more rapidly. However, this was offset in the drying of the expanded rubber to a greater extent than had taken place during the expansion. As a result the prosthesis assumed an accurate but enlarged pattern that was satisfactory for recasting into a final prosthesis for use on the patient.

Briefly, the expansion is accomplished by soaking the vulcanized rubber pattern in benzine until it has expanded to a degree slightly above that which is desired. It is then allowed to shrink somewhat to assume correct but enlarged proportions. The pattern is then used for plaster molding for the final rubber prosthesis or cast.

Expansion and contraction are also governed by the amount of filler (clay) in the rubber. The more filler, the greater the contraction. However, expansion takes place to a lesser degree if the cast is filled.

According to the record kept of experiments, the following results in expansion were noted. These experiments were done on rubber casts from plaster molds.

---

*From the Army Medical Museum.

Received for publication, March 1, 1943.

EXPERIMENT 1

Subject: Coin.

Materials: Vultex H-235 2 parts; Dixie clay 1 part

Expanding agent: Benzine

Minutes	Size in mm.	Expansion gain in mm.
0	40	0
45	55	15
65	58	18
80	60	20

This cast reached its maximum expansion of 60 mm. in 80 minutes.

EXPERIMENT 2

Subject: Coin.

Material: Vultex F-293 2 parts; Water 1 part

Expanding agent: Benzine

Minutes	Size in mm.	Expansion gain in mm.
0	40	0
15	60	20
60	70	30

From this experiment it will be noticed that the unfilled cast expanded more rapidly than the filled cast. In 15 minutes it reached 60 mm. in diameter, a 20 mm. gain. It reached its maximum expansion of 70 mm. in 60 minutes.

EXPERIMENT 3

Subject: Coin.

Material: Vultex H-235 2 parts; Dixie clay 1 part

Expanding agent: Benzine

Minutes	Size in mm.	Expansion gain in mm.
0	40	0
5	42	2
10	44	4
15	46	6
30	50	10
45	53	13
60	60	20
225	60	20

This cast reached its maximum expansion in 60 minutes. However, soaking was continued to see whether disintegration would take place. This became apparent as soaking continued over exceptionally long periods of time. Vulcanization plays a large part in the degree of disintegration. Unvulcanized casts disintegrate rapidly. The well-vulcanized cast holds up after prolonged soaking in benzine.

EXPERIMENT 4

Subject: Coin.

Material: Vultex F-293

Expanding agent: Benzine

Minutes	Size in mm.	Expansion gain in mm.
0	40	0
5	43	3
10	46	6
15	46.5	6.5
30	49	9
45	52	12
60	55	15
75	57	17
90	62	22

This cast was slightly thicker than the cast used in Experiment 2, therefore expansion took place more slowly.

EXPERIMENT 5

Subject: Prosthetic Nose.

Material: Vultex H-235 2 parts; Dixie clay 1 part

Expanding agent: Benzine

Minutes	Size in mm.	Expansion gain in mm.
0	74 high, 53 wide	0 high, 0 wide
21	82 high, 62 wide	8 high, 9 wide
45	85 high, 65 wide	11 high, 12 wide

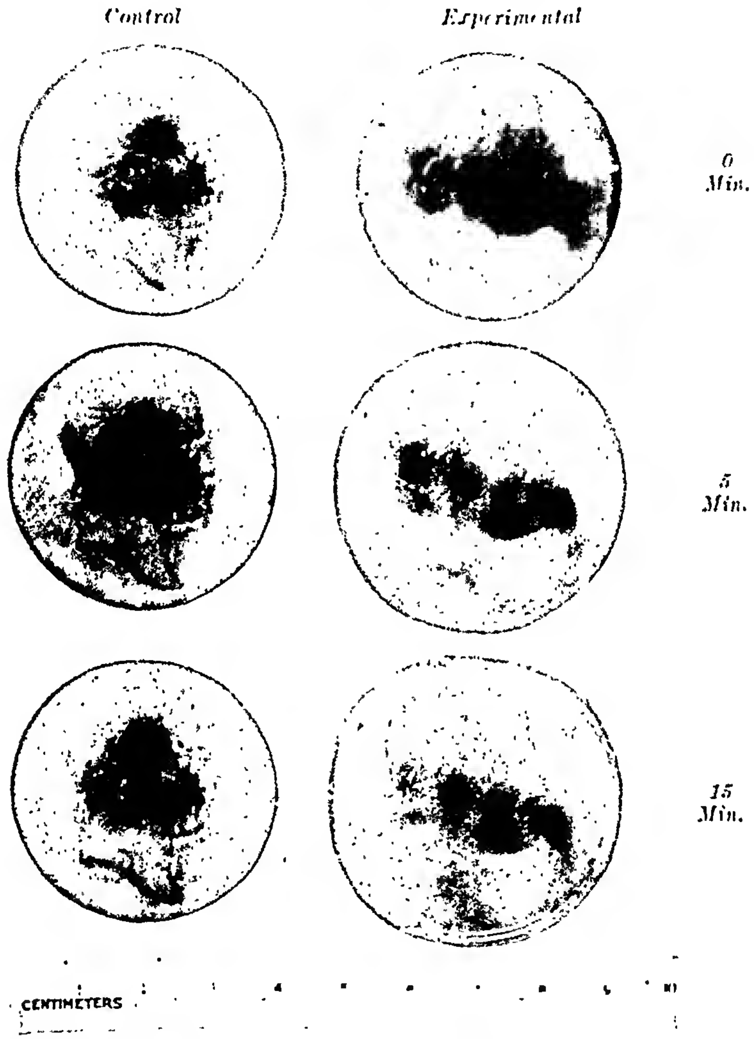

Fig. 1.—The control and experimental of vulcanized latex containing no filler. It will be noticed that after 15 minutes of soaking in benzine distortion begins to appear.

After 45 minutes in the benzine distortion began to take place, so the prosthesis was removed from the benzine. On examination it was found that expansion had taken place rapidly in the thin area. When the prosthesis was allowed to stand in the air it was found that on evaporation of the benzine shrinkage took place more rapidly in the thin areas than in the thick ones. Therefore, the model shrank back to a true ratio in the proportionate areas but there was an enlargement throughout the entire cast. The photograph in Fig. 3 was taken five minutes after removal from the benzine. It shows clearly the proportional

enlargement that is possible. This enlargement is greater than is necessary for prosthetic appliances because the natural shrinkage of rubber is not sufficient to offset such an enlargement. Although it may be necessary to enlarge prosthetic hands and arms beyond the actual size of the donor's hand to provide the

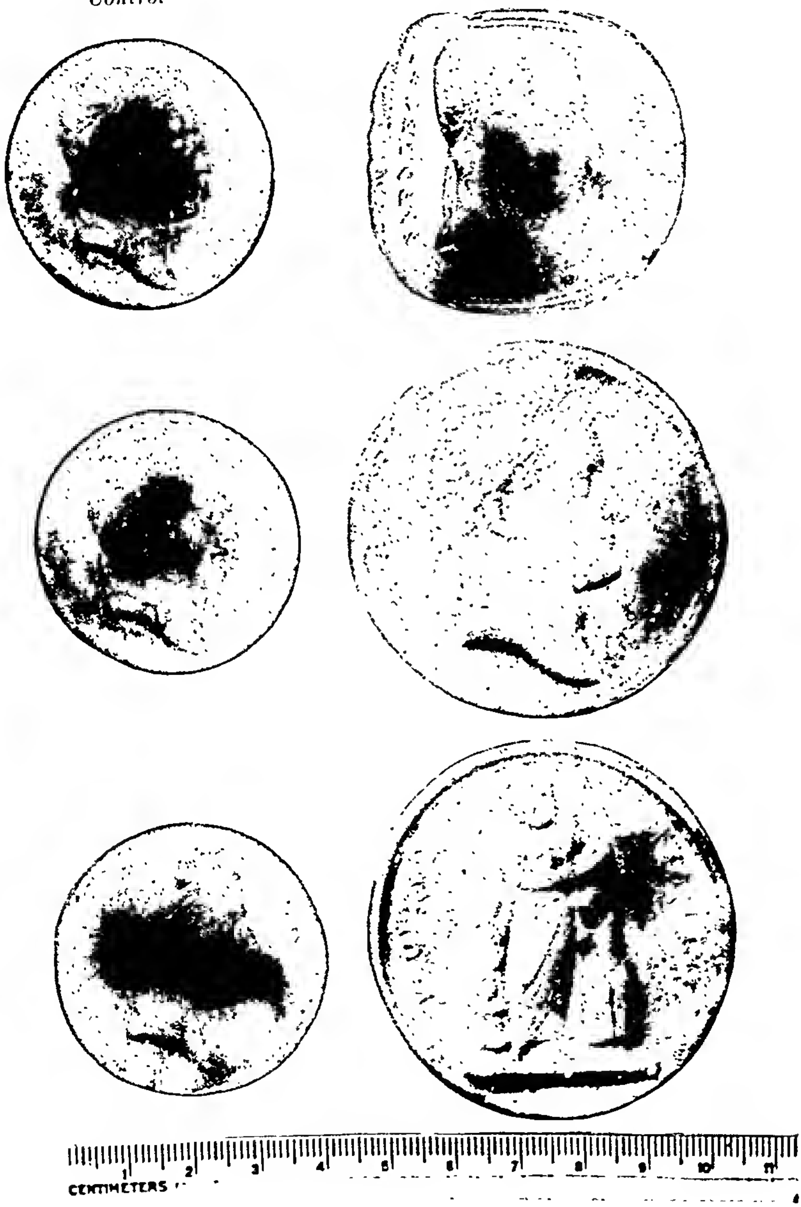

Fig. 2.—This is a continuation of the illustration seen in Fig. 1. Distortion has taken place rapidly in 15 minutes of soaking. At the end of 90 minutes the experimental has flattened without distortion. The bottom picture shows the reverse side of the coin.

correct size for the recipient, it is not likely that an enlargement of such proportions would be necessary in many cases. However, greater enlargements in true ratio and proportions are possible.

As mentioned previously, a distorted enlargement of greater proportions

was obtained in 45 minutes' soaking in benzine. Five minutes after it was removed from the benzine the prosthesis shrank to true but still enlarged proportions to the control. As the benzine continued to evaporate the prosthesis became smaller and eventually returned to the same dimensions as the control. This took about two hours. At any point during this shrinkage the model could have been remolded to obtain a permanent prosthesis of enlarged proportions that would not shrink appreciably regardless of time.

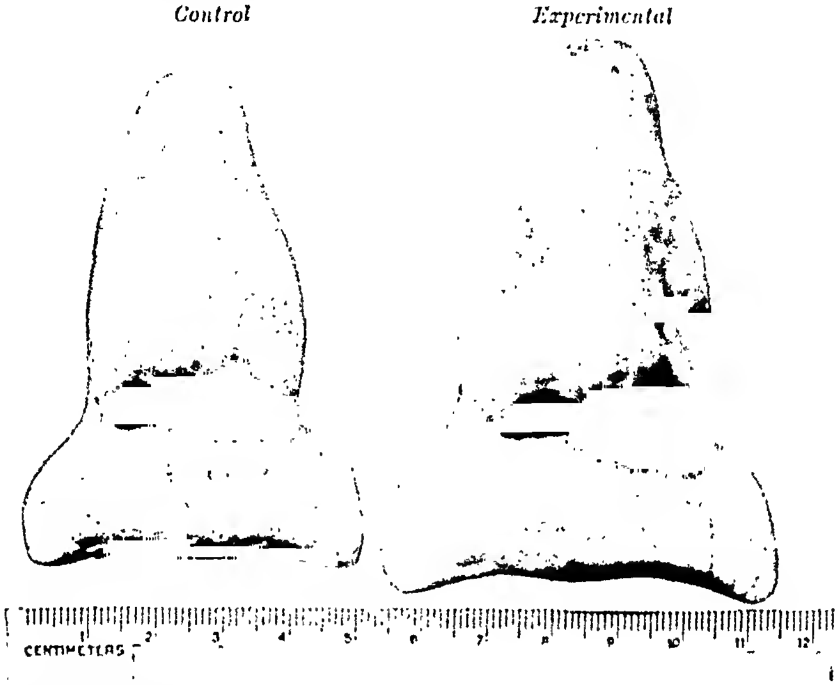

Fig. 3.—Rough casts of filled rubber prosthesis showing expansion in true proportions. This has expanded more than necessary, since it is only essential to offset normal shrinkage for this type of prosthesis. Filled rubber shrinks about 2 mm. to 40 mm.

Distortion.—Upon further investigation it was found that the experimental eventually assumed true proportions when it reached the saturation point during soaking in the benzine. Enlargement of nearly two diameters or roughly three times in area was obtained. The more filler used in the rubber latex the smaller was the enlargement. Nevertheless, this had little effect on distortion. As the enlarging process advanced the model lost physical strength but it always possessed enough toughness to be molded in plaster at any time during the soaking in benzine. In prosthetic hands the expansion can be held permanent for a longer period of time or shrinkage prevented by filling the rubber shell with a microcrystalline wax. This wax is pliable and permits the fingers to be moved in any position desired before molding. A one-piece plaster mold is then made of the rubber hand. After the plaster mold has set the wax is melted out. The collapsible rubber pattern shrinks and is finally pulled from the mold. This one-piece mold is used for pouring duplicate rubber hands to be attached to the patient. In this way prostheses without seam lines are obtained. This technique will be described more fully in a future article.

Accelerated Shrinkage.—Contrary to common belief it should be realized that rubber can be cast in practically any type of mold. This includes molds of agar, plaster, wood, cement, terra cotta, glass, rubber, and synthetic plastics.

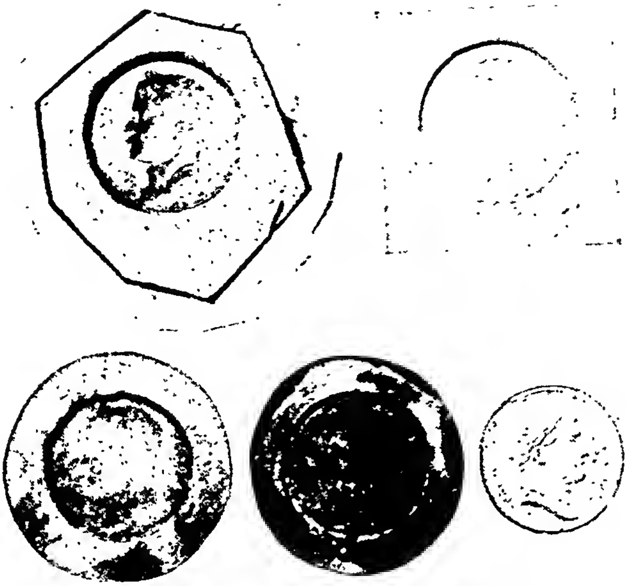

Fig. 4.—Rubber casts can be made from many types of molds. *Upper left:* An agar mold. *Upper right:* A plaster mold. *Lower left:* A wax mold. *Center:* A rubber mold. The small impression at the lower right is a rubber cast.

Fig. 5.—*Top left:* Original coin. *Top right:* First cast from a plaster mold. This cast contained no filler. It was used as a control. *Lower left:* The first cast from an agar mold showing a reduction. *Center:* A second recasting from an agar mold showing further reduction. *Lower right:* A third recasting showing a still further reduction. These recastings were of filled rubber and photograph better than the unfilled rubber which was nearly transparent.

In fact, the problem has never been with the molding material, but new separating mediums had to be devised to suit the mold. Rubber adheres to rubber, therefore soap and a salt acting as a coagulating agent for rubber had to be used on the mold. Rubber will not stick to agar. However, a coagulating salt had to be added to the agar mix to coagulate the rubber latex on the surface of the agar to build up a sufficient thickness of rubber to make the cast of practical use. The subject of separating and coagulating agents also will be discussed further in a future article. This subject has been considered in some detail in the book *Molding and Casting.*[1]

Shrinkage takes place more readily in casts that dry from the side next to the mold. Those that dry from the hollow side of the cast only, shrink less. For example, when rubber is poured into a dry plaster mold, water is absorbed from the latex mix into the porous mold. If rubber is poured into an agar, a rubber or synthetic plastic mold which is nonabsorbent, a rubber coating or layer must be built upon the mold. The excess then is poured out. This coagulated layer of rubber must dry from the hollow side. Furthermore, after coagulating it must not adhere to the surface of the mold. Both the inner and outer surfaces are exposed to the air and shrinkage takes place rapidly. This shrinkage can be offset to some extent by pouring over the coagulated and partially dried rubber layer a microcrystalline wax which presses the rubber back to the mold surface.

If a filled rubber latex is poured into an agar mold, proportional contraction or shrinkage readily occurs on the drying of the rubber. An agar mold will also quickly contract on drying. Here considerable distortion takes place in the mold. This distortion can be prevented by the addition of sorbitol to the agar mix. Shrinkage follows but it is not distorted contraction. In the first casting of a filled rubber latex positive in an agar mold containing no sorbitol a proportional shrinkage of 5 to 40 millimeters occurs, thus producing a cast of 35 millimeters in diameter. The second casting from a second agar mold of the first casting shrinks from 35 to 30 millimeters, and the third casting shrinks to 27 millimeters. Therefore, three castings into agar molds produce a proportional shrinkage of 13 millimeters. As a result, the final cast is reduced to nearly half a diameter of the original pattern. The same process can be continued without appreciable loss of detail.

Prinz[2] gives the following formula for reducing the size of plaster of Paris casts:

Alcohol	1 part by weight
Water	2 parts by weight
Plaster of Paris	enough to suit

The cast is allowed to dry for a few days in a warm place. After the alcohol has been evaporated completely, the finished cast will be about 1/25th smaller in all directions than the original model from which the impression was made. By repeating the process any desired reduction may be obtained.

The reduction of only 1/25th in this case is so small that the experiment was not done. At this rate many castings would be necessary to obtain the 1/8th reduction possible with one casting of rubber into agar. However, from a research standpoint Prinz's method may prove of value.

BOOK NOTICES

Fundamentals of Immunology*

UNTIL within the last decade medical writers have approached the subject of immunology chiefly through the medium of bacteriology. Most of the leading texts on the subject have dealt with bacteriology and immunology. Recent advances in the study of the nature of antibodies and the mechanism of their reaction with foreign cellular and noncellular proteins have been made especially through the medium of protein chemistry and physical chemistry. Dr. Boyd's book, "Fundamentals of Immunology," presents an adequate discussion of recent advances in this new phase of the study. It may be highly recommended as a reference volume on the mechanism of antigens, antibodies, and their interactions, and it is so constructed that it will also serve as a textbook and laboratory manual. The discussion of anaphylaxis is rather brief. That of clinical allergy is decidedly superficial, but this phase of the discussion was not the purpose of the book.

The discussion of antigen-antibody reactions includes study of blood groups, complement and complement fixation, and immune reactions to bacteria, viruses, and parasites.

Physiological Regulations†

DOCTOR Adolph's monograph, *Physiological Regulations,* deals chiefly with the study of the mechanism maintaining water balance in experimental animals and in man. It is highly technical and should be of chief interest to physiologists and biologists.

Familial Nonreaginic Food-Allergy‡

DR. COCA, like many other allergists, has long been conscious of the inadequacy of skin tests with food extracts. His new book, *Familial Nonreaginic Food Allergy,* describes a new approach to the study of allergenic foods. Some food extracts produce positive skin reactions which are truly reaginic. Others appear to give false negative reactions. Dr. Coca believes that these are nonreaginic. His experience has been that this type of food, when eaten by one who is sensitized to it, produces an increase in the pulse rate which can be used diagnostically.

Dr. Coca documents his thesis with detailed presentation of case records. He describes the technique of diagnostic study in detail, and outlines the program of practical management.

Irrespective of whether the author's theory concerning the effect of foods on the pulse rate will be substantiated by others, the volume covers the careful investigations of a leader in the field of allergy and will be of interest not only to allergists, but to internists and others.

Psychosomatic Medicine§

PSYCHOSOMATIC medicine may be termed the newest specialty in the field of internal medicine and psychiatry. The psychiatrist has in the past dealt with psychotics, many of whom are incurable, but has recognized the field of functional nervous disorders in which

‡Familial Nonreaginic Food-Allergy. By Arthur F. Coca, M.D., Medical Director, Lederle Laboratories. Cloth, 160 pages, $3.00. Charles C Thomas, Publisher, Springfield, Ill., and Baltimore, Md., 1943.

§Psychosomatic Medicine. The Clinical Application of Psychopathology to General Medical Problems. By Edward Weiss, M.D., Professor of Clinical Medicine, Temple University Medical School, P[illegible] [illegible]urgeon English, M.D., Professor of Psychiatry, Temple University Medic[illegible] Cloth, 687 pages, $8.00. W. B. Saunders Company, Philadelphia and [illegible]

supervised orientation may relieve the patient. It is in this group that the Freudian procedures of psychoanalysis and psychotherapy, used in the broad sense, are often helpful. The internist, on the other hand, treats many cases with organic disease in which he realizes that emotional factors play a part but which he is unable to study adequately because of too limited experience in psychotherapy. Collaborative efforts by the psychiatrist, or psychologist, and the internist may be expected to solve many of these patients' problems. Psychosomatic medicine may be loosely described as the treatment of emotional factors which color the symptomatology of somatic or organic disease.

The volume *Psychosomatic Medicine* results from the collaborative effort of an internist and a psychiatrist. The first two chapters deal with presentation of the problem, with description of illustrative cases. Reading these chapters, one will agree enthusiastically with the authors as to the need for a new method of treatment for such cases and is likely to conclude that the procedure should be very simple, just a matter of horse sense. The last four chapters describe the technique of psychosomatic study and treatment in detail. After reading them, one realizes that this is a highly technical field requiring extensive training, if the therapist wishes to do good rather than harm. Although psychosomatic practice will necessarily develop into a strict specialty, every physician practicing medicine should be well acquainted with the problems and methods in the field. This volume fills this need adequately. In it one finds discussions of the psychosomatic factors in cardiovascular disease, disorders of the gastrointestinal system, the endocrine system, the respiratory system, allergic diseases, the central nervous system, the genitourinary system, and disorders of sexual function. There is also a chapter on military medicine.

Man in Structure and Function*

MAN *in Structure and Function* is a two-volume semipopular discussion of human anatomy and physiology written by a German physician and translated by Dr. George Rosen. The text is free enough from technical terminology and complicated verbiage so that a well-educated layman, not averse to making the acquaintance of some new words, can read it with understanding. The fascinating part of the book, however, is its illustrations. These might be termed "inspired." They illustrate statements concerning the structure and especially the function of the body in the form of comparisons with familiar objects and experiences which all readers can understand with no difficulty at all. There are 461 of them. These volumes are worth their price for the illustrations alone.

*Man in Structure and Function. Volumes I and II. Translated from the German and edited by George Rosen, M.D. Cloth; Vol. I, 311 pages; Vol. II, 712 pages; $10.00. Alfred A. Knopf, New York, 1943.

COMMUNICATION

The first Women's Army Auxiliary Corps Hospital Unit, organized to replace able-bodied men in laboratories and hospitals of Army posts and stations, is now serving with the Army at Station Hospital, Fort Oglethorpe, Ga. This group of medical, surgical, and laboratory technicians, x-ray technicians, dental assistants, pharmacists, medical stenographers, clerks, and typists is expected to be the forerunner of other WAAC hospital units to be organized and sent out to Army posts. WAACs are also serving as technicians, hospital mess sergeants, cooks, and chauffeurs.

PROGRESS

NUTRITION IN THE WAR

FRANKLIN C. BING, PH.D.,* CHICAGO, ILL.

DURING the first World War emphasis was on food. Now it is on nutrition, for this is the science concerned with the proper use of foods for the development and maintenance of healthy, well-nourished bodies. A great deal of factual information has been obtained in laboratories and clinics on the composition of foods and on the dietary requirements in health and in disease. Work along some of these lines has been intensified because it has been recognized that additional information was needed without delay for the handling of wartime problems. The principal activity, however, has been in the application of nutritional knowledge gained through fundamental research. This field of applied nutrition has required the active participation of workers in many other fields. It is the purpose of the present article to describe some of the current important aspects of applied nutrition and to mention also some of the problems that are being investigated at the present time.

SPECIAL PROBLEMS INTRODUCED BY THE WAR

Feeding the Army and the Navy.—"An adequate dietary," Colonel Paul E. Howe[1] has written, "is important for the soldier's health, morale, and effectiveness." In the Army, the immediate responsibility for procurement, distribution, and preparation of foods rests with the Quartermaster Corps, while the supervision of the diet of the soldier is the responsibility of the medical officers in conjunction with the officers of the line. The effort has been to have the American soldiers the best fed troops in the world, and, from reports of

*Director of the American Institute of Baking. Formerly Secretary of the Council on Foods and Nutrition of the American Medical Association.

Received for publication, June 29, 1943.

Colonel Howe, in charge of nutrition activities for the medical department, this goal has been attained for men in training or in service in the United States. The records show clearly that the individual soldier is receiving all of the dietary essentials in quantities exceeding the recommended daily allowances of the Food and Nutrition Board of the National Research Council.[2] It is gratifying to know that the tremendous problem of feeding the American troops is being handled so successfully.

Reports on the feeding of troops in overseas service and in combat areas probably will not be forthcoming until after the war, but there is every reason to believe that the men are well taken care of nutritionally. Rations for use overseas have been described by Wodicka.[3] Considerable interest has developed in the combat ration known as Field Ration K, developed originally in response to a request from the parachute troops, but of such merit that it has proved to be of general usefulness as an emergency ration. Three different units are provided in durable containers which together weigh about two pounds. The foods consist of different types of biscuit, canned meat with cheese, and a beverage concentrate. Chewing gum and cigarettes are also included. The meat, confectionery and beverage concentrates are different for each of the three meals. The nutritive value of these three meals has been designed to meet the requirements of the men. In the development of this ration, the Subsistence Research Laboratory of the Quartermaster Corps, located in Chicago and under the direction of Colonel R. A. Isker, has shown considerable skill and resourcefulness.

In the development of other special rations, a considerable amount of investigation is still under way, and, naturally, the results of such studies have not been published as yet. In this work, experts and officials of the Army, Navy, Marine Corps, Coast Guard, and Merchant Marine work in close cooperation with the Committee on Medical Nutrition of the National Research Council, the chairman of which is Dr. James S. McLester. This Committee is able to supply or obtain quickly the best available opinion on scientific questions and to plan tests for developing the answers to problems that need experimental investigation. Frequently these investigations are made in university laboratories under contract with the Office of Scientific Research and Development. The Navy recently has developed a Naval Medical Research Center located at Bethesda, Maryland, where nutritional and other questions related to the many special problems confronting the Navy can be studied. The scientific director of the Naval research laboratories is Dr. A. C. Ivy.

The emphasis on foods for combat troops is on keeping quality, compactness for ease in shipping, palatability, for no food is of any value unless the men will eat it, and on nutritional value, because it is recognized that if the foods do not provide the nutritional requirements of the men, recourse will have to be had to other methods of meeting these requirements. Industry has cooperated wholeheartedly and importantly with these newer developments, and, in the production of dehydrated foods especially, and in the perfection of proper packaging for special conditions, great advances have been made. Undoubtedly some of the newer developments will be useful to the civilian population after the war.

Much attention has been devoted to the requirements of foods for use by shipwrecked personnel, by troops in desert or jungle areas, or wherever an emer-

gency ration is needed in situations requiring conservation of the available supply of water. It is well known that the ingestion of protein foods and of inorganic salts subsequently involves the excretion of urea and salts in aqueous solution through the kidneys, thus depriving the body of some of its water. It would seem desirable therefore to reduce the protein and mineral content of these emergency rations to a minimum, or to avoid these foods entirely in favor of carbohydrate and fat. The use of candy containing citric acid, a stimulant for salivary secretion, has been developed. It would seem, however, that the formulation of suitable dietary schemes for use under such conditions is one which might well attract many investigators who are not now engaged in war problems. Is a man floating in a rubber lifeboat on a tropical sea better off eating nothing rather than eating fish which he may be able to catch? What should be the nature of the emergency foods provided? These are important nutritional questions.

There are many problems concerned with the feeding of men who are exposed to unusual environmental conditions, as in service on submarines or in airplanes. Bierman[4] has discussed the problems of aviation medicine concerned with air sickness, obesity, and the expansion of gases that form in the intestinal tract at higher altitudes. The condition of air sickness develops as a rule from acceleration during flight. It is considered to be a functional neurosis characterized by vomiting, nausea, apprehension, faintness, sweating, and sometimes prostration, and it may be precipitated or aggravated by the sight or odor of food. Men appear to be specially prone to develop air sickness on an empty stomach or after a heavy meal, and therefore Bierman has suggested that the meals should be light and served at four-hour intervals. Obesity in the aviator is undesirable, because fat affords an excellent storage for nitrogen and hence appears to aggravate the development of "bends" at high altitudes. The expansion of intestinal gases at high altitudes may cause intense discomfort and cramps that may persist for as long as twenty-four hours after returning to sea level. The elimination of gas-containing foods and beverages and those foods which are known to be particularly prone to develop flatus helps to avoid this difficulty, as does the feeding of frequent light meals. There is evidence that vitamin C is of considerable importance in enabling men to fly at high altitudes. The relationship of vitamin A to visual acuity, especially in dim light, is less clearly defined, but it is universally admitted that the rations of all military personnel should be thoroughly adequate with respect to all the vitamins and other dietary essentials, and a high content of vitamin A is desirable.

The value of the administration of additional vitamins when the diet itself is adequate with respect to these factors has been experimentally studied by Keys,[5] with negative results. On the other hand, there is accumulating evidence to show that the ability to perform work is decreased on low thiamine diets and improved following the administration of thiamine under these conditions. Thus on diets providing about 0.33 mg. of thiamine and 0.5 mg. of riboflavin daily, Foltz, Barborka, and Ivy[6] showed clearly that the work output was decreased and the subjects complained of lack of vigor, anorexia, and leg pain. When the deficient diet was supplemented with suitable quantities of yeast concentrate, providing thiamine, riboflavin, and other members of the B complex, there was a

prompt increase in the work output and a disappearance of the symptoms. At the Fatigue Laboratory at *Harvard University*, Egaña,[7] Johnson,[8] and their co-workers have also observed a close relationship between an adequate amount of thiamine and the ability to perform muscular work.

Problems Concerning the Feeding of Civilians in the United States.—The problem of meeting the civilian requirements for good nutrition is much more involved than the problem of feeding the armed forces. An excellent discussion of food supplies and public policy, food production and distribution is provided in the series of articles published under the title of "Nutrition and Food Supply: The War and After" in the Annals of the American Academy of Political and Social Science for January, 1943. Agencies of government have been established with the view of guiding agricultural production of foods and the distribution of foods in the wisest possible manner. The complexity of the problems involved may be illustrated by the situation which developed with corn in June, 1943. Because of prevailing ceiling prices, an editorial in the Southwestern Miller[9] states that farmers could anticipate obtaining about $1.50 for the pork produced from feeding about $1.00 worth of corn to hogs. As a consequence there developed a shortage of corn for human food purposes and for industrial needs and a tremendous increase in the hog population. The products of corn are needed not only for the manufacture of corn meal, cornstarch, certain breakfast cereal foods, and other foods such as corn sirup and dextrose, but also for the growth of significant amounts of the yeast used in the making of bread and for materials used in the manufacture of explosives, aluminum, magnesium, bronze, steel, and other war products. By the middle of June the War Food Administration had taken emergency steps to help relieve the situation and to enable essential war production to continue.

The rationing of foods has been developed to permit a more equitable distribution of foods in short supply. These include meat and butter and other fats, the supplies of which are being used in large part for military and lend-lease purposes, and sugar and coffee which must be imported. Canned foods have been rationed because they also are being used for military and lend-lease purposes and because any marked increase in production would involve the use of strategic materials and manpower. The reason for requiring ration coupons for evaporated milk is said to be in order to place this important food under control. Serving in an advisory capacity to help assure that rationing regulations of the Office of Price Administration will be in the interests of continued health of the people is the Civilian Food Requirements Branch of the Food Distribution Administration, of which Dr. Russell M. Wilder is Chief.

In the rationing of foods for civilians, consideration must be given to nonfood uses, the requirements of food industries, restaurants, and institutions, and the requirements of consumers. The general policy has been to keep rationing regulations as simple as possible. There is a trend also to give preference in the materials allocated to industrial users to those manufactured foods where foods in short supply help further the use of those articles the supply of which is more abundant. In the allocation of relatively scarce items to industrial food processors, some consideration has been given also to the nutritional importance of the finished products.

People ordinarily learn about the nutritional value of foods from various sources, among which is advertising. Guidance of food advertising along educational lines long has been a concern of the Council on Foods and Nutrition of the American Medical Association. Realizing the importance of such work, the government has established a plan of cooperation with advertisers of food products known as the War Nutrition Program under the supervision of Drs. M. L. Wilson and W. H. Sebrell of the Nutrition Division of the Office of Defense, Health and Welfare Services of the Federal Security Agency, the administrator of which is the Honorable Paul V. McNutt. Early in 1943 the Nutrition Division was transferred to the U. S. Department of Agriculture and is now known as the Nutrition and Food Conservation Branch of the Food Distribution Administration. There has been a commendable trend on the part of food manufacturers and distributors to show in their advertising how the food article which they are selling fits into the scheme of an adequate diet for health. A new chart recently has been developed which describes seven basic food groups that should be included in the diet each day in the interests of good health. Thus advertisers of foods, in contributing to the National Nutrition Program, will be presenting the same basic information about the characteristics of an adquate diet.

Feeding Industrial Workers.—Recognition of the importance of the problem of feeding industrial workers is evidenced by the fact that at least three important committees have been established for the consideration of questions that arise in this field. The Food and Nutrition Board of the National Research Council has a subcommittee on the Nutrition of the Industrial Worker, and the Councils on Foods and Nutrition and on Industrial Health of the American Medical Association have formed a cooperative committee on Nutrition in Industry. The Office of Defense, Health, and Welfare Services maintains a division on Nutrition in Industry, which functions largely through the regional representatives and the State nutrition committees that have been established under the supervision of this agency. Close cooperation exists between this department and the Industrial Hygiene Division of the United States Public Health Service. A number of informative reports have been published and several research projects have been organized for the purpose of answering questions in this field. As Goodhart[10] has pointed out, a great burden of the work must be borne by local nutrition committees. The industrial nurse and the industrial physician often can help immeasurably in solving the immediate problems of an industry.

Surveys by Wiehl[11] of the diets selected by aircraft workers in California have shown the choice of foods to be exceedingly poor and it is reported that the condition has become worse rather than better. She found that if one assumed values equal to two-thirds of the recommended dietary allowances of the Food and Nutrition Board to be a minimum value for adequacy, the diets selected by these workers were deficient as follows: about 15 per cent were low in vitamin A, 25 per cent in calcium, over 40 per cent in riboflavin and in ascorbic acid. Medical appraisal of the nutritional status of such workers has afforded a comparable picture of deficiency, certainly a condition that is not conducive to continued maximum output of war materials. The principal weapon for overcoming such deficiency would appear to be education, but in the case of the

industrial worker, it is possible, and no doubt essential, to do more than that. It has been pointed out that in many plants, particularly the smaller ones, there are no facilities whatever for providing the workers with lunch or with mid-shift meals. Indeed the tendency is to keep the amount of time for eating to a minimum. The carrying of lunches or other packages into some of the larger war plants is prohibited because there are inadequate facilities for inspecting the contents of such packages. The manner in which some firms have met these problems and a discussion of other current nutritional activities in industrial establishments has been provided by Cowgill.[12]

Considerable interest has been aroused in connection with the question of giving all industrial workers vitamin preparations. In reviewing the evidence on this subject, a Joint Committee of the Council on Foods and Nutrition and of the Council on Industrial Health of the American Medical Association expressed the view that such indiscriminate administration was economically unwise, nutritionally unsound, and therapeutically irrational.[13] This Committee believes that much of the vitamins so administered would be wasted, and it expresses the opinion that vitamins could not correct all possible dietary deficiencies and holds to the conviction that the administration of vitamins is best handled under medical supervision, especially by the practitioner who has had an opportunity to examine the individual patient and thus to ascertain his requirements. More recently the argument has been advanced that the giving of vitamins now is desirable because of food rationing and because the vitamins in themselves will do no harm. Except for vitamin D, large doses of which may produce untoward effects, it is correct that the vitamins will do no harm. On the other hand, it is still questionable whether under the usual conditions contemplated for the administration of vitamins on a mass scale, they would accomplish as much good as would be accomplished by attention to the diet. Further, the supply of vitamin preparations is not inexhaustible, and increased production of thiamine, riboflavin, and ascorbic acid requires equipment, strategically important chemicals, and manpower.

THE NUTRITIONAL STATUS OF THE PEOPLE

A recent report[14] of the Committee on Diagnosis and Pathology of Nutritional Deficiencies, of the Food and Nutrition Board of the National Research Council, entitled "The Prevalence of Inadequate Diets and Deficiency States in the United States Together With a Consideration of Their Significance" asserts that every survey in the past decade has revealed widespread dietary deficiencies in the United States. It has been argued, however, that surveys of food consumption do not necessarily give a true picture of the condition of health of the people, and medical records have been cited to show that the incidence of malnutrition is almost insignificant. A discussion of the discrepancy of these two views has been presented by Jolliffe, McLester, and Sherman,[15] who have given reasons why national mortality tables and hospital admission rates tend to present an overly optimistic picture. Space does not permit a discussion of the results of newer methods of medical appraisement of the nutritional status, particularly because some of the methods are not yet firmly established; but probably every critic would agree that the diet on the whole is not as good as it ought

to be, and could be, and that the work of applying nutritional principles to practical human problems must be continuously carried on. The problem now as before is to teach people the principles of proper eating. There is insufficient evidence to judge the effects of rationing on the general nutritional status of the people in the United States. Some persons believe that the present situation has served to focus attention on the need of selecting foods on a nutritional basis. We are assured also that even with rationing the American dietary is adequate in quality and quantity of nutrients.

Great Britain.—A number of reports have indicated that the nutritional status of the people in Great Britain is, on the average, probably better than it was before the war.[16] If this is correct, it is likely that rationing schemes which guarantee the more equitable distribution of foods have been in large measure responsible. Since early in 1942 all infants, expectant mothers, and small children have been receiving daily some sources of vitamins C and D at least during the winter months. These groups also received extra rations of milk. Arrangements have developed so that people unable to afford these foods are given them just the same.

Although the overall picture is gratifying, it is true that some groups which before the war were better fed are in poorer nutritive condition today because of rationing. Body weight is said to be somewhat below the usual weight. The tuberculosis rate, however, has not changed markedly. There is some evidence that the incidence of anemia has increased, although the iron content of the diet probably is greater than it has been previously. The principal weakness in the British diet today, however, is in its vitamin C content. Although evidence of scurvy has not been observed, the people are living on diets very close to or below the minimum requirement of 30 mg., which is considered to be the amount necessary to prevent scurvy. The recommended daily allowance for the normal adult in the United States is considered to be 75 mg. Steps undertaken to correct this condition have been the encouragement of planting home gardens of green leafy vegetables and the utilization of unusual foods such as rose fruits which are relatively rich in ascorbic acid. In this connection, a recent report of Hunter and Tuba[17] in Canada is of interest. They found that edible products could be made from rose hips available in Canada, and it can be calculated that the expected harvest from Alberta would be sufficient to supply 140 million people (being equal to the population of the United States) with 100 mg. of ascorbic acid daily for a year.

THE OUTLOOK

With all of the attention that is being devoted to the subject, it is not overly optimistic to believe that the allied nations will come out of the wor with their nutritional status unimpaired and perhaps in many instances improved. Evidence of the fact that the nutritional point of view is taking hold is apparent to every close observer. Agricultural economists are beginning to speak occasionally of the nutritional yield of an acre of ground. Programs of agricultural production are laying considerable emphasis on the desirability of agriculture being geared to meet the nutritional requirements of the people. Laboratories have been established for the examination of soils and varieties of plants with

a view to ascertaining the kind of treatment of soils and the varieties of plants to select in order to reap the maximum nutritive value from the crops. Commercial processors of foods are becoming more and more concerned with the nutritive value of their products. Studies are being undertaken with a view to ascertaining the facts and then taking steps to conserve to the highest possible degree the nutritive value of the natural foods from which the processed foods are made. Notable in this connection is the program of the National Canners Association and the Can Manufacturers Institute on the nutritive value of canned foods.[18]

Fortification of foods has been placed on a sound basis,[19] as a result of considerations given by bodies such as the Council on Foods and Nutrition of the American Medical Association and the Food and Nutrition Board of the National Research Council. Of the common staple items there are only four classes of foods to which general approval has been given as vehicles for the administration of vitamins or minerals or both. These are enriched white flour and enriched white bread, which provide additional amounts of thiamine, niacin, and iron and, when supplies become available, of riboflavin, oleomargarine containing added vitamin A, iodized table salt, and vitamin D milk. The most recent of these developments has been the enrichment of flour and bread, and data now are available to show the value of this procedure.[20, 21]

In connection with the fortification of foods, mention should be made of the important work that the Food and Drug Administration of the Federal Security Agency, under the able leadership of Mr. Walter G. Campbell, has been doing. Definitions and standards have been developed for many common foods as well as for the fortified foods already mentioned, thus aiding "in protecting the public against exploitation by programs dictated more by commercial motives than by public interest."

Recently hearings have been concluded for the purpose of receiving evidence necessary to amend the standards for enriched flour and bread in accordance with recommendations of the Food and Nutrition Board of the National Research Council. Students of nutrition will find a study of the records of these hearings to be of great interest. The findings of fact relative to the higher enrichment levels for flour have been published.[21b]

A POSSIBLE WORLD-WIDE NUTRITION PROGRAM

Professor John D. Black[22] of the Department of Economics at Harvard University has written of the importance of nutrition in the postwar years in the following words: "All the knowledge of foods and nutrition that we now have must in due time be turned to the task of restoring order and building up a peace that will not be menaced by hunger and deficiency diseases." This concept of nutrition as a potent factor in harmony among nations in a postwar world was specially emphasized at the United Nations Conference on Food and Agriculture recently concluded at Hot Springs, Virginia. Probably the average person who has read only the newspaper accounts of this Conference is familiar with only two facts that were widely publicized: the fact that newspaper representatives were not admitted to executive sessions, and the report that considerable amounts of whisky were shipped to Hot Springs while the conference was

in progress. It does not seem to be generally known that there were representatives of 44 governments present, 9 of which were occupied by enemy nations. Though none of these delegates had the power to make agreements for the governments which they represented, it would seem likely that the agreements they did make as a result of the discussions at this meeting will be more binding than have been many of the treaties arranged by diplomats. The Conference probably was the first in history for the discussion of postwar planning while a war was in progress. Attention was directed, not to the requirements of individual countries, but to the rights of the individual human being. There were three sections to the Conference, and Section 1, which was concerned with problems of nutrition and public health, adopted a number of resolutions on May 29, 1943. Can anyone read the following account[23] of the first resolution adopted by this Section without realizing that nutrition is recognized as a factor of dominant importance for health?

The United Nations Conference on Food and Agriculture

having reviewed the information submitted by the several delegations on consumption deficiencies and the relation of food to health through the world and being deeply impressed by the dominant role played by adequate food in the reduction of sickness and death rates and the maintenance of health, the Conference

DECLARES:

1. That the first essential of a decent standard of living is the provision to all men of those primary necessities which are required to promote freedom from disease, and for the attainment of good health;
2. That the most fundamental of these necessities is adequate food which should be placed within the reach of all men in all lands within the shortest possible time;
3. That ample evidence has been presented revealing the existence of malnutrition in every country, with its inevitable consequences of preventable ill health; and

RECOMMENDS:

That the governments and authorities here represented:

(a) Immediately undertake the task of increasing the food resources and improving the diets of their people in accordance with the principles and objectives outlined in the findings of the Conference, and declare to their own peoples and to other governments and authorities here represented their intention of so doing;

(b) Undertake periodically to report to one another through the permanent organization recommended in Resolution II on the state of their national nutrition and on the steps being taken for its improvement.

It is of special interest to note the desire for immediate action in improving the diets of people and, in this connection, it should be stated that the delegates of the occupied countries were in favor of the resolution but desired that a footnote be added to explain that, obviously, countries in the hands of our enemies could not begin such a program right away.

CLINICAL AND EXPERIMENTAL

THE PRINCIPLES OF PERCUTANEOUS ABSORPTION*

Stephen Rothman, M.D., Chicago, Ill.

Absorptivity of the skin has widespread implications in different branches of medicine such as physiology, pharmacology, toxicology, topical and systemic therapeutics, dermatology, industrial hygiene, balneology, and forensic medicine. Consideration of the fact that it may become important in war medicine also prompts a review of the subject at this time.

Electric Forces Regulating Absorption.[1]—On sending a direct current through the human body by means of metallic electrodes the initial intensity of the current drops considerably within fractions of a second, as if there were a sudden increase in ohmic resistance ("pseudoresistance of the skin"). This phenomenon is due to polarization, i.e., to the generation in the body of a current which flows in a direction opposite to that of the original current. The polarization current is produced in the epidermis exclusively. It fails to appear if the continuity of the epidermis is disrupted. It can be obtained in its full strength in the isolated epidermis.

If a direct current has to pass a membrane in a solution of electrolytes, a new electromotive force is produced, originating from the difference in diffusion-velocity of electrically positive cations and negative anions wandering through the membrane (electric diffusion potentials). Often the membrane is permeable only for either cations or anions, in which case a high potential difference may develop by the "electric double layer" on both sides of the membrane. This is the case with human epidermis which has a negative charge and is impermeable for anions.[2] Consequently aqueous solutions of electrolytes do not penetrate the epidermis.

If the isolated epidermis is used as a diaphragm in a vessel filled with water and a direct current is sent through the water, there is a movement of the water from the anode to the cathode.[3] This movement of water through membranes is called electroendosmosis. Its direction is towards the cathode if the membrane has a negative charge. By addition of salts or acids to the water the epidermis, or any other membrane with a negative charge, becomes discharged, and the movement of water is slowed down or stopped entirely. By addition of alkalies which increase the negative charge the movement is accelerated.[3]

The membrane effect of the epidermis is due not to the stratified structure of the Malpighian layer with its many layers, but to a single membrane being in

This article is based on an earlier review of the subject[1] in which references previous to 1932 are quoted extensively. In this review the references will be restricted to publications of major importance of the period from 1920 to 1941.

Received for publication, January 29, 1943.

immediate contact with the electrolyte solution.[2] The horny layer cannot be regarded as a membrane in the electrophysiologic sense, because it represents a rather rough network of horny lamellae with large holes in it, and therefore is easily permeable for ions as well as for large molecules.[1] The electrical behavior of the skin is not influenced by extreme thinning or thickening of the horny layer. Therefore the seat of the polarization phenomena is to be placed in the transitional layers between cornified and noncornified epithelium (stratum granulosum and stratum lucidum). These layers are responsible for the polarization current ("pseudoresistance") and for the impermeability of the skin to electrolytes.[3] They are called the barrier of skin absorption. Being situated between the strongly acid stratum corneum and the slightly alkaline Malpighian layer, they represent an electric double layer with positive hydrogen ions on one side and negative hydroxyl ions on the other side.[1]

Functional changes alter the electrical behavior. Mechanical, chemical, thermic, and electric stimuli cause a diminution of the skin resistance ("local galvanic reactions").[4] This phenomenon is due to changes in the cell membrane causing increased permeability and decreased polarization currents. This condition can be demonstrated in any inflammatory lesion of the skin if the lesion is due to primary damage of the epidermis. Hyperemia due to vasomotor reflex does not change the resistance.

Misconceptions on Transepidermal Absorption.[1]—The surface of the skin is covered by a greasy layer consisting mainly of waxes and cholesterol esters.[5] The role of this covering as a factor in the impermeability of the skin for water and electrolytes has been overestimated. It is true that it hinders the wetting of the cornified surface, and so delays the penetration of water and aqueous solutions into the horny layer. Waxes and cholesterol esters are miscible with water, however, and therefore after prolonged contact with water, particularly with warm water, the permeation of aqueous solutions into the horny layer becomes possible. The keratin material swells in water as it is grossly seen on palms and soles where the thick horny layers show abnormal wrinkling and a whitish discoloration after a prolonged bath.

Similarly to the role of the greasy cover the role of the horny layer has been misinterpreted as a barrier for percutaneous absorption. Its large pores are permeable not only for water and aqueous solutions but for molecules of any size and even for gross molecule aggregates.

A third misconception is the idea that increased blood flow may facilitate the percutaneous absorption of substances which normally do not penetrate. This belief has arisen from the observation of qualitatively increased permeability in inflammatory lesions. Such increase is due to epidermal injury, however, and not to increased blood flow. If once the barrier of transepidermal absorption in the epidermis is broken through by any injury and a substance has entered the living epidermis, its absorption into the blood stream is no longer prevented. Increased blood flow may accelerate the rate of absorption but does not change the permeability of the skin qualitatively.

Absorption Through Appendages.[1]—The mechanism of percutaneous absorption as a whole becomes rather complicated by the presence in the skin of gland ducts and hair follicles which open on the surface in the form of visible

pores. The hair shaft does not adhere to the follicular wall. The space between is loosely filled with greasy, horny scales and contains air. This space is continuous with the duct of the sebaceous gland which empties the sebum into it. Any substance may penetrate this space and reach the duct of the sebaceous glands, and from there the gland cells. This pathway does not require passage through a stratified epithelium but leads through a canal filled with air to cell membranes, the permeability of which is higher than that of the transitory epidermal cells. Similarly, through the sweat gland ducts any substance may reach the secretory surface of the sweat gland cells after having passed the straight and the convoluted part of the duct. When a substance has reached the secretory cells, it easily enters the blood stream, even though it is true that a "basal membrane" has to be passed before the endothelium of the capillaries is reached.

Water and aqueous solutions do not enter the follicular and glandular pores by mere capillary attraction because of insufficient wetting and because the ducts are filled with air. Under pressure, however, the adherent air may separate and escape in form of bubbles as can be seen during a warm bath. In the case of inunction of ointments, compression of the air in the duct and absorption of the air through gland cells may take place.

Experimental Conditions and Methods.—As has often been emphasized, in experiments on percutaneous absorption the intake of substances through the respiratory tract and through the mucous membranes of mouth, rectum, and vagina has to be carefully avoided. Working with volatile substances, i.e., substances with relatively high vapor pressure, one must be particularly cautious to avoid errors in attributing absorption through the lungs to percutaneous absorption.

To prove that percutaneous absorption of substances foreign to the body has taken place, analytic-chemical methods should be preferred to any other method in demonstrating the presence of these substances in tissues, in the blood, or in the excretions. If, in lack of chemical methods, pharmacologic or toxicologic assays have to be used, such assays must be unequivocally specific for the substance in question. Histochemical methods, often used to prove the permeation of a substance into the skin proper, are sometimes of dubious reliability, and one should be particularly critical in evaluating the results obtained with such methods.

For experiments on the absorption of substances normally present in the body, the procedure of Hediger[6] is the method of choice. With some modifications it has been widely used by Bürgi[7] and his co-workers, with consequent valuable contributions to the subject matter. In this method the solutions to be examined are applied to the skin under glass bells with airtight occlusion, and changes in the concentration of the dissolved substances are estimated at certain time intervals in aliquot parts by quantitative chemical analysis of the fluid above the skin. Decrease of concentration indicates percutaneous absorption of the solute. The time curve of the rate of absorption can also be easily determined by this method.

Absorption of Water.—The bibliography of experiments on water intake through the skin of human beings is old and obsolete. Plethysmographic meas-

urements on a limb enclosed air tight in a water bath for several hours do not show any decrease in the volume of water.[1] It is conceivable that negligibly small amounts of water, within the error margin of the plethysmographic method, may enter the pores after having expelled the air. Practical experience, however, especially experience with the permanent "water bed" of the dermatologists, supports the assumption that the amount of water intake under normal pressure is extremely small, if any. Intake of water through the epidermis certainly does not take place. Whereas the horny layer swells throughout its whole thickness when a limb is kept in water, the living epidermis cells remain microscopically unchanged. It has been assumed that the pH of the cell proteins in the transitory layers between the cornified and noncornified epithelium is identical with the isoelectric point of these proteins which therefore are unable to swell in water.[1]

Absorption of Electrolytes.[1]—It can be stated as a general rule that electrolytes dissolved in water do not penetrate the skin of mammals. This impermeability is fairly well understood from the physicochemical point of view as discussed previously. The theory of pores in the cell membrane based on model experiments[8] furnishes a most satisfactory explanation for the impermeability of the skin for anions. Membranes with extremely fine pores adsorb selectively, depending on the electric charge, either cations or anions, and therefore these "ion sieves" are impermeable for electrolytes. Tiny canals in the cell may correspond with such pores.

The easiest way to demonstrate the impermeability of the skin to aqueous solutions of electrolytes is to apply to the skin salts, which normally are not present in the body, and to determine whether these compounds, if applied to the skin, are excreted with the urine. Salts with nonphysiologic cations, such as salts of lithium, cesium, rubidium, and strontium, were tested in this way. They were applied to the skin in aqueous solutions in the form of baths, sprays, etc., but none of them could be recovered in the urine.[1, 9] The impermeability of the skin for salts containing the physiologically occurring cations sodium and calcium has recently been proved by means of Hediger's method.[10]

Of the anions the iodide anion was tested most frequently. With iodides the experimental results were not unequivocally negative. In a few experiments traces of iodine were recovered in the urine after iodides had been applied to the skin in aqueous solutions. The iodide ion has a relatively good chance to enter the skin, because, in comparison with the chloride ion, it is an anion which increases the negative electric charge of the skin and its capacity of swelling in water.[1] Also, there is some evidence that small amounts of iodides may be oxidized to free iodine in the skin and be absorbed in this form.[11]

It has been shown histologically that if there is any absorption of iodides the route is through the appendages. Whether or not this route is passed, however, may depend on different conditions in the secretion of sebum, different degree of filling of the ducts, number and size of follicles, ducts, and glands, air content, etc. The mucous layer is absolutely impermeable for iodides. The same is true for salts in general. In principle their absorption through appendages cannot be said to be impossible. Practically, however, such an absorption does not amount to more than questionable traces.

Salts of bi- and trivalent cations, especially heavy metal ions with a low electromotive force, are partly lipoid-soluble and therefore absorbable by the skin. They will be dealt with among the other lipoid-soluble substances.

Percutaneous Absorption of Water and Salts in Different Species.[1]—In lower species intake of food and output of metabolic end products are partially functions of the skin but with the phylogenetic development of the animal world the physiologic importance of absorption through the skin has gradually decreased. There is only one basic difference between percutaneous absorption in lower and higher species, however, and this concerns the absorption of water. The skin of invertebrates, fishes, and amphibians does absorb water but that of mammals does not. As for electrolytes, the tegument of even the lowest animal is impermeable if the tegument is at physiologic rest. During the period of nutrition through the skin and during the excretion of metabolic end products there is a temporary increase of permeability.

Absorption of Lipoid-soluble Substances.—The "lipoid theory" of absorption (Overton[1]) has postulated that the cell membrane consists of lipoids because only lipoid-soluble substances may penetrate the cell. Also, according to this theory the penetration of a substance quantitatively depends on the degree of its solubility in lipoids. This theory was critically reviewed in an excellent article by M. H. Jacobs.[12] Also, he amplified the theory by relating the solubility in lipoids to the nonpolar structure of organic molecules.

As far as absorption in general is concerned, many exceptions to Overton's rule were found.[12] Practically no exception could be established for absorption through the skin, however. Qualitatively it has been proved that lipoid-soluble substances penetrate the skin, whereas substances insoluble in lipoids do not. Quantitatively, however, this rule cannot be carried through consistently. Some substances slightly soluble in lipoids penetrate with greater ease than others with higher lipoid solubility. Some authors suggest that a certain degree of solubility in water together with high solubility in lipoids is optimum for absorption through the skin.[13] In other words, a certain ratio of the solubility in water and in lipoids may be the decisive factor; e.g., alcohols, aldehydes (chloral hydrate, paraldehyde), and ketones (acetone), soluble in both lipoids and water, penetrate with great ease.

The idea that the permeability to lipoid-soluble substances is due to a sterol-phosphatide framework in the cell or in the cell membrane was reviewed and experimentally supported in 1936 by Starkenstein and his co-workers.[14] These authors confirmed and supplemented earlier incomplete observations[1] which indicated that any disturbance of the lipoid framework either by precipitation or by dissolution of cholesterol breaks up the barrier of skin absorption. Previous treatment of the skin with chloroform or ether, which dissolve cholesterol, or with saponins, which precipitate it, makes the skin permeable for water-soluble substances and diminishes the permeation for lipoid-soluble compounds. On the other hand, introduction of cholesterol into the skin, for instance with ointments, diminishes the permeability for water-soluble substances because the cholesterol wall has been strengthened.[15] In fact, from a table of my earlier work[1] in which the data on the absorption of potassium iodide from different ointment bases are listed, it is obvious that the absorption is poorer from bases containing cholesterol than from bases without it.

The number of lipoid-soluble substances which have been proved to penetrate through the intact skin into the general circulation is too large to be exhaustively listed in this article. Only a few of the medically important groups of lipoid-soluble substances will be discussed, namely phenolic compounds, lipoid-soluble heavy metal salts, hormones, vitamins, alkaloids and fatty ointment bases.

The percutaneous absorption of phenol was well known to physicians of the older generation. They witnessed severe and sometimes fatal poisoning following the application of carbolic acid to large areas of the skin. Such unfortunate events did not occur frequently, however, and the popularity of this kind of treatment was not decreased for some time. Many doubted its being dangerous at all. What is more, in a very recent discussion on the permeation of phenol the question again arose as to whether its external application may cause any systemic effect.[16] The reason for this uncertainty in a problem settled a long time ago may be found in the fact that phenol in high concentration coagulates the proteins of the skin, and combines with them to form large molecules, the lipoid solubility and penetration capacity of which are completely different from those of free phenol. It should be stated here as a general rule that *any substance when applied in a high concentration having a caustic effect is absorbed in relatively smaller amounts than when the same substance is applied in lower concentrations which do not elicit a gross response.* This has been proved not only for phenol[17] but also for a number of heavy metal salts[17, 18] and for hydrogen sulfide.[19] In addition, it has been shown that previous treatment of the skin with caustics[18] or with astringents[20] decreases the permeability to other absorbable substances.

Salicylic acid (o-hydroxybenzoic acid), the most frequently tested substance in experiments on percutaneous absorption, penetrates with extreme ease through the skin from aqueous and alcoholic solutions as well as from ointments. Lipoid solubility is a property of the nondissociated molecule and not that of the salicylate ion. Sodium salicylate which is ionized in aqueous solutions is not lipoid-soluble, and does not penetrate the skin unless there is enough carbon dioxide in the tissue to liberate salicylic acid from the salt.[1, 21] The esters of salicylic acid, used externally as antirheumatic preparations, are lipoid soluble and penetrate easily.[1, 22]*

Other lipoid-soluble phenol derivatives such as resorcin, hydroquinone, pyrogallol also enter the skin from any vehicle.[16]

Of the lipoid-soluble salts of heavy metals, mercuric bichloride was often found to be absorbed from its aqueous solutions through the unbroken skin. Similarly to phenol, however, its penetration is interfered with by its coagulating effect on proteins when applied in concentrations above 0.5 per cent.[18] From the literature of past decades one may obtain the impression that systemic mercury poisoning from external application of the bichloride occurred frequently when it was used in medicated baths. One has to consider that this method of therapy was usually applied in disorders involving broken skin, however, and that with the disrupted barrier massive absorption might have occurred.

*Wintergreen oil used as a solvent increases the absorption of other lipoid-soluble substances considerably.[17]

The penetration of the skin by lipoid-soluble salts of lead such as lead acetate and lead oleate has been shown to occur from aqueous solutions.[13] The amounts absorbed are small (0.1 to 0.2 milligram daily from a 10 centimeter-square area), and it has been doubted whether they have any importance in industrial hygiene in the matter of causing clinically manifest poisoning. These traces of lead, however, as an addition to the amount absorbed by the respiratory and digestive tracts, may do their share in the development of lead poisoning.

As does lead, copper enters through the skin into the general circulation when applied in the form of its lipoid-soluble fatty acid salts, for instance copper-oxyoleic acid.[23]

Salts of lead, tin, copper, arsenic, bismuth, antimony, and mercury tend to form compounds with the fatty acid radicals of the sebum and other fats of the skin surface. Thus an originally lipoid-insoluble compound in aqueous solution may be transformed on or in the horny layer into a lipoid-soluble substance. The percutaneous absorption, then, is due to, and quantitatively dependent on, this chemical transformation. The same reaction may take place outside of the body to a larger extent if the heavy metal salt is incorporated into ointment bases which contain fatty acids. This is one reason for the increased absorption of heavy metal salts from ointments as compared with their absorption from aqueous solutions.

Because of the great therapeutic importance in dermatology of ammoniated mercury (mercuric aminochloride) its percutaneous absorption has been the object of numerous investigations. Ammoniated mercury is insoluble in water, in lipoids, and in lipoid solvents. Its bactericidal effect is based on its adsorption to the cell walls and on an extremely slow dissociation of mercuric ions under the influence of the acid reaction of the horny layer and sweat.[24] Its absorption into the general circulation is practically nil.[1, 24-27] In careful studies Gibbs and his co-workers[28] have shown that any appreciable percutaneous absorption of mercury from ammoniated mercury ointments is due to gastrointestinal absorption following contamination of the oral cavity. In adults where contamination of the mouth is much less likely to occur than in children, systemic mercury poisoning is practically never seen after the use of ammoniated mercury ointments, even if the ointment is applied daily for months or years over the whole skin surface. A few isolated cases of such poisoning which have been described[29] apparently were based on extreme hypersensitivity to mercury with traces causing poisoning.

Percutaneous absorption of vitamins and hormones strictly follows the law that any lipoid-soluble substances are absorbed through the unbroken skin in measurable amounts. Most extensive studies on absorption of lipoid-soluble hormones have been carried out with sex hormones. These studies were reviewed by Eller and Wolff in 1940.[30] It seems to make scarcely any difference quantitatively whether these hormones are given in injections or in form of ointments because the total amount is absorbed in either case. The speed of absorption is different, however, the percutaneous absorption usually being slower. The lipoid-soluble vitamins A and D and the provitamin carotene behave in the same way as do lipoid-soluble hormones.[30] The fact that irradiation of the skin with ultraviolet rays is a substitute for the intake of vitamin D in the therapy of rickets is sufficient proof of the percutaneous absorption of vitamin D.[31]

In connection with the findings on the fast permeation of lipoid-soluble vitamins and hormones the old problem once more emerged as to whether percutaneous application of drugs has any advantage over the peroral and/or parenteral ways. Such an advantage is present only if one wants to create a slowly but steadily increasing level of the drug in the blood and tissues up to a certain maximum which may then be kept constant by daily inunctions. In the past the classical mercury inunction in the treatment of syphilis was advocated mainly on this basis, although similar absorption rates and concentrations have been achieved with intramuscular injections of insoluble salts ("depot effect"). Obviously such an advantage is not sought in the case of administration of hormones and vitamins. The aim of such therapy is saturation of the deficient organism. The saturation may be achieved through the administration of the lacking factor in any mode of application, and the speed of absorption is of no great importance. If anything, rather rapid absorption is desirable in vitamin and hormonal deficiencies.

Another reason for percutaneous drug application, however, is to create a higher concentration of the drug in a certain region of the body. It has been claimed that such an effect occurs, e.g., when salicyl-ester preparations are rubbed into the skin locally above the painful muscles in myalgia. There is little doubt that introduction of a drug into the skin may temporarily cause a relatively high concentration of the drug in the tissues close to the site of application, although in reference to muscles this never has been conclusively demonstrated. When in the treatment of deep-seated organs local percutaneous therapy appears to be superior to systemic administration, this superiority results from local vasomotor reflex processes rather than from higher drug concentrations.

In the skin itself a locally higher concentration at the site of application has been unequivocally proved by the unilateral swelling[32] and unilateral hyperpigmentation[33] of the nipples in response to unilateral application of estrogenic hormone. It goes without saying that the principle of topical dermatotherapy as a whole rests on the creation of a locally high concentration of drugs in the skin without appreciable systemic effect.

In a few unduplicated experiments the lipoid-insoluble and water-soluble vitamins, ascorbic acid,[34] and thiamin chloride ("betaxin"),[35] were found to penetrate the skin. These unexpected results should not be discussed here as no confirmation could be found in the literature.

From the extensive work on percutaneous absorption of insulin[36-40] one can conclude that under carefully controlled experimental conditions negative results are prevalent. Positive results are due either to skin injuries from shaving in animal experiments[38] or to a preparatory treatment of the skin with chemicals (alkalies,[40] benzine petroleum,[41] saponins,[42, 43] irritant plant extracts[44]) which pathologically increase the permeability of the skin.

The free alkaloid bases are lipoid-soluble and penetrate the skin. Their water-soluble salts do not penetrate. For instance, nicotine, strychnine, and opium alkaloids[17] are absorbed with great ease but not their sulfate or hydrochloric salts. The impermeability for the salts of alkaloids, like that of inorganic salts, is not absolute, but only traces go through, and these only after ap-

plication for many hours. The alkaloid base in the same amount and concentration may kill the animal in a few minutes. Of anesthetics nupercaine and pantocain were claimed to have the highest capacity of penetration.[45]

It has been known since 1879 that animal and vegetable fats and oils penetrate the skin via the pilosebaceous apparatus.[1] They enter the circulating blood after having been absorbed by the sebaceous gland cells. These cells excrete microscopically visible fat droplets as their function. In viewing their structure one is not too surprised to see the reverse process also take place, namely, the intake of roughly dispersed fat by their protoplasm.

It has also been known for a long time that mineral fats and oils enter the sebaceous glands and are absorbed systemically, although their absorption is not nearly so massive as that of animal and vegetable oils and fats. All these facts have been confirmed many times, most recently by Eller and Wolff[16] in detailed and careful experiments.

Penetration of animal, vegetable, and mineral fats through the epidermis proper never has been conclusively demonstrated. Fats are not "lipoid-soluble" in the narrower sense of the term, because they form not true but colloidal-disperse solutions with fat solvents.[1] Absorption from such solutions seems to be impossible for any living cell except sebaceous gland cells. Lanolin and paraffin are not absorbed by the epithelial cells of the intestines either,[1] and triglyceride fats are absorbed along this route only after they have been split into fatty acids and glycerin.

Absorption of Water-Soluble, Lipoid-Insoluble Nonelectrolytes.—Theoretically such absorption is not to be expected through a membrane which is impermeable to water. Experimentally it has been shown that sucrose[46] and galactose[47] do not penetrate from ointments, and it is highly probable that glucose does not either. It is regrettable that the available data on this problem are deficient and unsatisfactory.

Immunologic and allergic experiments seem to indicate that lipoid-insoluble antigenic substances which usually are large molecules or molecule aggregates may enter the skin from ointments.[48] This unexpected result, however, has been achieved only after rubbing the antigen-ointment vigorously into the skin for fifteen minutes. It has been stated that such treatment irritates the skin. A skin area treated in this way cannot be regarded as normal. It must also be considered that in the sensitized organism traces of the antigen are sufficient to elicit the immunologic reactions which have been used as indicators for the absorption of the antigens. That their absorption is not great in amount is indicated by recommendations to increase it either by previous treatment of the skin with benzene and petroleum benzine,[49] or by electrophoretic introduction,[50, 51] or by the use of the newly described penetrasols of Herrmann, Sulzberger, and Baer.[69]

Absorption of Gases.—Substances which are in the gaseous form at room temperature easily penetrate the skin with the remarkable exception of carbon monoxide which is insoluble in lipoids.[1] Ease of percutaneous absorption has been demonstrated for the following gases: oxygen,[1, 52] nitrogen,[53] helium,[53] carbon dioxide,[1, 10] ammonia vapor, hydrogen sulfide,[1, 10] hydrogen cyanide,

vapors of nitrobenzene, dinitrobenzene, dinitrotoluene,[1] and vapors of volatile aromatic oils.[17]

When hydrogen sulfide is applied to the skin in irritating concentrations, its absorption is relatively smaller than in low concentrations.[19] Experiments with aqueous solutions of hydrogen sulfide at various pH's[54] have revealed that the nondissociated H_2S molecule penetrates better than do the HS^- or NaS^- ions. Ammonium sulfide, however, seems to penetrate better than hydrogen sulfide.[55] If elemental sulfur is applied to the skin in ointment vehicles, its absorption occurs in the form of sulfides.[56] Cases of poisoning after treatment with sulfur ointments have been reported as due to this mechanism.[57] The manifestations are those of hydrogen sulfide poisoning.

The absorption rate of oxygen and carbon dioxide at constant temperature and pressure depends exclusively on the difference in the concentration of these gases within and outside of the skin.[1, 52] This absorption thus represents a simple physical diffusion process. This is probably true also for gases foreign to the body. The finer mechanism of this diffusion process has not been studied in detail. Its importance for toxicology and industrial hygiene is evident.

The Role of Vehicles.—Substances soluble in both water and lipoids such as salicylic acid or mercuric bichloride penetrate with great ease from aqueous solutions as well as from ointments or from fat solvents. Although usually the absorption from fats and fat solvents is more rapid and more complete than from water, this is not a general rule. It has been found, for instance, that estrogenic and androgenic hormones are better absorbed from aqueous vehicles than from oil.[30, 58] Such findings indicate that the permeation of a substance depends primarily upon its own (total or partial) lipoid solubility. The kind of vehicle into which it is incorporated and the solubility of the substance in the vehicle are of secondary importance.

The use of fat solvents, such as ether, chloroform, benzene, petrol-benzine, and, to a lesser degree, alcohol, usually enhances the percutaneous absorption considerably. This action is due not to the high solubility of lipoid-soluble substances in these solvents, however, but to the fact that these solvents in themselves increase the permeability of the skin. If the skin is treated with them in advance, i.e., previous to the absorption experiment, an increased absorption is subsequently observed from aqueous solutions as well as from any other vehicle. The classical experiments of Winternitz[1] with aqueous solutions of strychnine salts have proved this fact, and more recent observations have confirmed his results.[14]

Organic solvents may accelerate absorption by dissolving the greasy cover of the skin surface and of the follicular wall, thereby facilitating the wetting of these surfaces by aqueous solutions. This action is a minor factor, however. The main action of these solvents lies in their dissolving of lipoid compounds in the living cells themselves, thus disrupting the barrier of absorption.

Ointments.[1]—Ointments are fats or similar substances of a greasy consistency. They are applied to the skin with or without incorporated drugs, mainly for therapeutic purposes. Ointments can be spread over the skin in a continuous thin layer. This cannot be done with aqueous or alcoholic solutions, because their surface tension working against a low viscosity causes

diminution of the surface, and formation of drops with disruption of the layer results.*

In order to bring the thinly spread ointment layer close to the uneven surface of the skin, a pressure must be exerted. By the pressure the gas bubbles adherent to the pores escape sideways; deeper in the follicles and gland ducts, they become compressed and absorbed. Applying the same pressure, one will obtain a closer contact with the surface if the viscosity is low, i.e., if the ointment is flexible and supple. Ointments which have a high viscosity and cannot be spread in thin layers are called tenacious or tough.

Numerous data have been presented indicating that incorporation of a substance into an ointment increases its rate of absorption in comparison with the absorption from other vehicles. Such an effect is mainly due to the mechanical factors as described. One presses the ointment into the follicle, and thereby brings the substances more rapidly and in larger amounts to the absorbing surface of the sebaceous gland cells than is possible with other vehicles. The ointment bases are absorbed through the appendages exclusively, and therefore they can increase the absorption of incorporated substances only via this route. The importance of the mechanical factor is indicated by the fact that absorption is furthered more readily by supple ointments than by tenacious ones.

Although ointments are helpful in bringing the incorporated substance closer to the surface of absorbing cells, *there is no evidence that either ointments or any other kind of "vehicle" may serve as a transportation vehicle into the cell itself.*[14] If we choose a substance to which the skin is completely impermeable, e.g., sodium salicylate, we are unable to enforce absorption even with the most supple ointment and despite extreme pressure.[1] Data are available indicating that vehicle and incorporated substance are absorbed separately and at different rates of speed. It was found, for instance, that from the metallic mercury ointment (blue ointment) at first more of the ointment base and later more of the mercury was absorbed.[59] In addition, some experimental results indicate that the incorporated substance has to separate from the ointment base before it enters the cell; the greater the tendency to separation, the more intensive is the absorption.[60]

The problem of determining the composition of an ointment which would attain the maximum absorption of incorporated substances has received much attention. With the exception of the requirement of suppleness no general rule could be established. It has been shown that for various substances different ointment bases are optimal.[56] In general, however, the addition of cholesterol as an emulsifier does not favor absorption.[15]

Considering the importance of low surface tension and of thorough wetting of the follicular wall it was to be expected that application of the modern wetting agents (synthetic detergents) would enhance percutaneous absorption considerably. This was demonstrated recently by W. Duemling.[61]

Chemical reactions between substances and ointment vehicles may increase absorption, if by such reactions lipoid-insoluble substances are transformed into

*There are two surface tensions to be dealt with: one between skin and liquid, and the other between liquid and air. Both act in the same direction if the liquid does not wet the skin, as is the case with water. With alcohol the two tensions act in opposite directions; nevertheless, formation of drops occurs.[1]

soluble ones. The most common chemical reaction is the formation of fatty acid salts (soaps) from neutral salts.

Electrophoresis.[1]—By applying a galvanic current to the skin, substances can be introduced into the circulation which otherwise would not penetrate or would do so only in traces. "Electrophoresis," meaning electric transfer, is the most suitable term for this procedure because it does not involve any assumption concerning its mechanism. The term "cataphoresis" is properly reserved for the transport of colloidal particles in an electric field. The expression "ion transfer" or "iontophoresis" involves the assumption that only ions are transferred in one direction or the other depending on their charge. The term excludes the transfer of nondissociated molecules. "Electroendosomosis" is defined as the movement of a liquid through an electrically charged membrane under the influence of a galvanic current.

Attempts to utilize electrophoresis in clinical therapy can be traced back to the middle of the last century. Again and again it was rediscovered and was believed to accomplish more than other methods of application. In spite of some interesting results, such as histamine electrophoresis in myalgia and mecholyl iontophoresis in arthropathia, the therapeutic achievements of electrophoresis have been rather meager up to date. Possibly, more recent efforts to utilize this method in diagnostic procedures[50, 51] will be more successful.

The method of clinical electrophoresis is simple. The two poles of the galvanic current are connected with aluminum or zinc plates which are covered with gauze. The "neutral" electrode is soaked with some inactive electrolyte solution, usually tap water. It is firmly applied anywhere on normal skin, or it is clipped to the inside of an insulated vessel (enamel bowl) filled with tap water into which the patient's limb is immersed. The "active" electrode has a relatively small surface, thus producing a high electrical density, i.e., high milliamperage per square unit area. After its gauze has been soaked with the solution to be introduced, the active electrode is pressed and firmly fixed to the skin area to be treated, or anywhere on the skin surface if systemic effects are sought. A current of varying intensity from a few tenths of a milliampere up to 40 milliamperes (in the average 1 milliampere per 1 cm. square area) is then sent through the body for a period of time varying from a few minutes up to one-half hour.

When substances are introduced into the skin electrophoretically, both ion transfer and electroendosomosis are involved. The mechanism of ion-transfer is well understood. If the biologically active part of an electrolyte is a cation, the drug is applied to the positive pole (the anode), and the cation will travel toward the negative pole, i.e., towards the inside of the body. The inactive anion will travel in the opposite direction, i.e., from the soaked gauze to the metal electrode. Similarly, a substance with an active anion will penetrate to the inside of the body from the negative pole (cathode). Thus iodide and bromide ions are easily introduced from the negative pole, metal ions and alkaloid-cations from the positive pole.

Electroendosmosis, the transport of the liquid as a whole, however, interferes with this simple mechanism.[2, 3, 62] The skin has a negative electric charge, and therefore electrophoresis will effect a movement of water into the body from the positive pole, and toward the outer surface of the skin at the negative pole.

A gross clinical sign of this movement of water is a shrinking of the skin pores at the positive, and a swelling at the negative pole after intensive electrophoresis. In case of cation-transfer from the positive pole, electroendosmosis acts in the same direction, thus facilitating the absorption of the cation. The anion-transfer from the negative pole, however, is counteracted by endosomosis, which elicits a movement in the opposite direction.

Difficulties encountered in the introduction of dye anions ("acid dyes") were interpreted as being due to the lack of endosmosis in the same direction.[62]

The role of endosmosis was proved by experiments indicating that any factor which furthers electroendosmosis also favors electrophoretic introduction from the positive pole.[3, 62, 63] Such factors are the addition of sucrose or of alcohol to the aqueous solutions of drugs or dye stuffs containing an active cation, factors which are unfavorable for ion-transfer but enhance electroendosmosis. On the other hand. high salt concentration or acidification has an opposite effect; they are unfavorable for electroendosmosis and greatly hinder permeation through the skin.

In contrast to cation-introduction, the entrance of anions is furthered if electroendosmosis is suppressed by the addition of acids, of multivalent cations or by concentrated salt solutions. The addition of sucrose or alcohol inhibits the entrance of anions.

The effect of electrophoresis on percutaneous absorption has been studied mainly with respect to aqueous solutions of dyes and alkaloid salts.[1] A great many of the latter, such as salts of strychnine, morphine, and atropine which have no demonstrable effect when painted on the skin in aqueous solution, display their characteristic general toxic effects after a short time when they are introduced electrophoretically in the same amounts and concentrations. The electrophoretic introduction of other drugs may be demonstrated by local effects at the site of entrance. Local vasoconstriction by epinephrine salts, local sweating by salts of acetylcholine, mecholyl, and pilocarpine, and local anesthesia by salts of cocaine cannot be produced by simple application of their aqueous solutions to the skin but are easily achieved by introduction with the galvanic current. The decided effect of electrophoresis on skin absorption was demonstrated dramatically by Leduc in 1900.[1] A rabbit painted with a solution of strychnine nitrate survived this treatment without the slightest signs of poisoning, whereas another rabbit into which the same solution was introduced electrophoretically died in a few minutes from strychnine poisoning.

In spite of this remarkable effect of electrophoresis one has to keep in mind that application of galvanic current does not alter the essential principles governing skin absorptivity. Aqueous solutions of electrolytes enter the skin in traces through the appendages without the use of any current. If an aqueous solution of strychnine nitrate in high concentration is painted on the skin over large cutaneous surfaces and for a long period of time, it will pass the appendages in amounts which eventually will kill the animal.[1] The electric current serves only to increase this absorption through the appendages, but it does increase it tremendously. Under the conditions of medical electrophoresis, the current carries aqueous solutions through the appendages exclusively and not through the epidermis. With respect to dyes this principle was demonstrated as early as 1890,[1] and has often been confirmed since.[64, 65]

Under conditions favorable for electroendosmosis in the electrophoretic experiment, an aqueous solution may enter the Malpighian layer, but then, as shown in experiments with dyes, the solution penetrates through the follicular wall and not through the surface epithelium.[62] In other words, the barrier in the follicular epithelium which has a histologic and physicochemical structure similar to that of the surface epithelium, offers less resistance to the current than does the epidermal barrier. The latter forms the greater obstacle.

The electric current itself also travels through the appendages. If applied to the skin with electrodes which are soaked with saline solution previous to the absorption experiment, the current will increase the absorption of aqueous solutions which are subsequently painted on the skin. This effect is due to decrease of polarization. Decrease of polarization, however, is a minor factor if galvanic; i.e., noninterrupted direct current is applied.[1] The main effect of electrophoresis is the great increase of absorption through the appendages without qualitative change of the permeability of the skin.

Absorption Through Diseased Skin.[1]—The study of absorption through pathologically changed skin corroborates the basic rules of percutaneous absorption: (1) The thickness of the horny layer is of no importance (normal absorption occurs from ichthyotic skin); (2) the fatty cover of the skin is irrelevant (there is equal absorption from seborrheic and dry skin); (3) the barrier is in the epidermis (destructive lesions of the epidermis eliminate the physiologic barrier); (4) the most important way of absorption is through the appendages (decreased absorption occurs in scleroderma and other processes with associated atrophy of the appendages).

Recent Contributions.—Miescher[65] studied the penetration of water-soluble fluorescent dyes by applying them in different vehicles to the skin of laboratory animals. The depth of cutaneous penetration was noted by observing frozen sections under the fluorescence microscope. He found only diffusion into the upper loose horny layer, and thus corroborated the existence of a barrier at the lower level of the stratum corneum. Furthermore, he confirmed the observations indicating that the thickness of the horny layer is of no influence on the absorption through the skin.

The increasing use and extreme efficiency of topical application of sulfonamides in war surgery justify the interest in their percutaneous absorption. Recent experimental work[66] has shown that sulfanilamide penetrates the intact skin from organic solutions. Sodium and calcium salts of sulfathiazole enter the skin from aqueous solutions and from ointments; they also can be introduced electrophoretically.[67] On the basis of what has been said in this review, the lipoid-soluble sulfonamides may be expected to penetrate the skin from organic solvents and ointments. Aqueous solutions of the sodium salts should be applied to the intact skin only by electrophoresis. One cannot expect, however, that the electrophoresis of the sulfanilamide anion from the negative pole will be sufficiently effective, because of the antagonistic effect of the opposite direction of the forces of electroendosmosis.

Herrmann, Sulzberger, and Baer[68] have recently introduced new types of vehicles. These vehicles were designed to increase percutaneous absorption by combining the properties of fat or lipoid solubility, water solubility, surface-

wetting action, and actions as solvents and homogenizers. An example of such a combined vehicle and solvent consists of xylene (or derivatives), a synthetic wetting agent, antipyrine (for solution and homogenization), and propylene glycol. In their preliminary report, the authors have called vehicles of this type "penetrasols."

The authors state that these pentrasols accelerate the penetration of a great variety of substances through grossly intact human and animal skins (sulfonamides, heavy metals, so-called protein allergens, etc.). The reviewer is of the opinion that the effects reported exceed those to be expected by simple lowering of the surface tension and by thorough wetting of the surface (see. p. 19). The penetrasols developed by Sulzberger, Herrmann, and Baer may achieve their effects by attacking the lipoid frame of the living epidermal cells in a manner similar to the effect exercised by saponins.

A SIMPLE LIVER PREPARATION ORALLY EFFECTIVE IN THE TREATMENT OF HUMAN AMYLOID DISEASE*

JAMES LOUKIDES, B.SC., HAROLD G. GRAYZEL, M.D., AND
MENDEL JACOBI, M.D., F.A.C.P., BROOKLYN, N. Y.

ORALLY administered powdered whole liver can effect the resorption of experimentally produced amyloid in animals,[1] and can effect an apparent clinical cure in human beings with secondary generalized amyloidosis.[2] In the latter paper it was shown that the administration of such a liver preparation caused the amyloid to disappear, despite the continuing activity of the incitant inflammatory disease.

Many requests for the liver product or its method of preparation have come to us from physicians all over the country. The liver powder used in our original work is no longer available, the concern producing it having ceased operation. We have tried the leading commercial liver preparations, but have found them unsatisfactory in the treatment of secondary amyloidosis. We therefore believe that a brief description of a method of preparing a "liver cocktail," with which we have had results as good as those with the powdered liver originally used by us and which is inexpensive and easy to prepare, is in order.

METHOD OF PREPARATION

Liver obtained fresh from an abattoir is cleansed of its gross extraneous matter, especially gross blood vessels. It is then cut into cubes and passed

*From Neponsit Beach Hospital for Children, Jewish Hospital of Brooklyn, and Beth-El Hospital, Brooklyn, N. Y.

Received for publication, November 27, 1942.

through a Sep-Ro-Siv.* The very fine sieve of the latter is used, the liver forced through the machine several times in order to reduce the product to a fine, pasty consistency.

Fruit juices are added to wash as much of the liver as possible through the sieve of the machine. The finely mashed liver will protrude through the pores of the sieve, while any attached tough muscle, fibrous tissue, or large blood vessels will be extruded through the end of the funnel. This residue from the funnel should again be put through the machine several times, for it thereby helps clean the teeth of the grinder of considerable retained valuable liver mash. A spoon is finally used to free the sieve of adherent macerated liver.

The pressed tissue and the juice are collected in a bowl. Additional fruit juice is added to thin out the mixture, and this is then passed through a fine scoop sieve that can be purchased in any five-and-ten-cent or hardware store. The finished mash should be totally free from lumps of liver. It generally resembles a chocolate drink in color. The taste is that of the fruit juice used, is quite palatable, and is taken readily. A mixture of orange and pineapple juice is the vehicle most popular with our patients; any juice, however, may be used to suit the patient. The liver preparation should be kept in a cold refrigerator or icebox. In the event that the drink is too thick, additional fruit juice may be added to suit the patient's demand. At certain times of the year the liver may have a pungent taste. Washing one's mouth with unadulterated fruit juice, or chewing a few gum drops will easily and rapidly overcome this taste.

This procedure gives an approximate yield of 90 per cent. The dosage varies from the equivalent of ¼ to ¾ of a pound of liver daily. Wherever possible, the use of mash prepared daily is recommended. We have found, however, that a three-day supply kept at a temperature of 8° F. or lower is equally potent and palatable. After four or five days the juice becomes mildly sour. Two pounds of liver and one quart of fruit juice yield a total of about two quarts of the final mash, a supply sufficient for three days.

COMMENT

We have found this fresh whole liver preparation effective against amyloid. It has the advantage of being simple to prepare and of being far less expensive than any commercial product. It has the disadvantage of requiring a rather tedious and time-consuming procedure, and of daily preparation or, at most, at intervals of three days. Conscientiously adhered to, the yield in quantity and potency of the product is high, and the drink is pleasant in appearance and taste.

There should be no possibility of ingesting parasites in the liver if the material is obtained from a reliable slaughterhouse and the liver is carefully examined as it is cubed. We have found no parasites in any of our liver preparations after prolonged and careful search, including microscopic examination of the product.

THE PROPHYLACTIC USE OF SULFANILAMIDE IN CHILDREN WITH RHEUMATIC HEART DISEASE*

CHARLES R. MESSELOFF, M.D., AND MILTON H. ROBBINS, M.D.,
NEW YORK, N. Y.

IN JANUARY, 1939, Coburn and Moore,[1] as well as Thomas and France,[2] published independently their observations on the prophylactic effect of sulfanilamide in rheumatic children. Stimulated by their favorable results, we began, in September, 1939, to administer sulfanilamide to a group of children attending our cardiac clinic. This communication is a report of the result of our study.

SELECTION OF CASES AND PROCEDURE

Observations were begun on children with inactive rheumatic heart disease who were attending the clinic. As the study progressed, a number of children were eliminated from the treated group and transferred to the control group because of (1) the appearance of mild toxic effects of sulfanilamide, or (2) lack of cooperation by either the child or the parent.

In all, 55 children were observed. There were 25 children in the treated group, and 30 in the control group. They varied in age from 6 to 14 years at the time of the beginning of the study. A study of Table I will show that, using the age of 12 years as the beginning of puberty, both groups consisted of almost equal numbers of pre- and postpuberal children.

TABLE I

AGE DISTRIBUTION AND SEX OF TREATED AND CONTROL PATIENTS

AGE	TREATED GROUP	CONTROL GROUP
6-8	1	3
9-11	12	9
12-14	12	18
Total	25	30

	TREATED GROUP		CONTROL GROUP	
	BOYS	GIRLS	BOYS	GIRLS
Number:	12	13	17	13

From the outset, we followed one method of medication: 5 grains (0.3 Gm.) of sulfanilamide were given 3 times daily for a period of one week, and if no toxic signs or symptoms appeared, the dose was increased to 10 grains (0.6 Gm.) in the morning and in the evening. This dose was maintained for the remainder of the study.

*From the Cardiac Service of the Hospital for Joint Diseases.
Received for publication, January 29, 1942.

The drug was administered during two treatment seasons: (1) from September, 1939, through May, 1940, and (2) from September, 1940, through May, 1941. The actual period of treatment during each season was about eight months.

A complete blood count, sedimentation rate, and an electrocardiogram were obtained on each child prior to the initial administration of the drug. Throughout the period of observation, blood counts and sedimentation rates were obtained at two- or three-week intervals. At similar intervals, a careful history and examination were done to determine the presence either of ill effects of sulfanilamide or of evidence of rheumatic activity. The children in the control group were seen, on the average, every three months unless a rheumatic recrudescence occurred. In such instances, the children were seen more frequently.

TOXIC EFFECTS OF SULFANILAMIDE

We can corroborate the observations of Thomas and her co-workers[3] that the serious toxic signs and symptoms which are not infrequently noted following the administration of large doses of sulfanilamide are not seen when small daily doses are taken. Thus, cyanosis, severe hemolytic anemia or granulocytopenia, severe dermatitis, febrile reactions, were not seen in our series. Minor toxic effects, however, were observed in ten children. Recovery was prompt and complete in every child following cessation of therapy. Indeed, experience has shown that recovery may take place in some children even if the drug is continued. We did not deem it justifiable, however, to expose ambulatory children to the continued effect of sulfanilamide in the presence of even minor drug reactions.

It is of interest to record, briefly, the toxic effects observed in our group.

1. *Anorexia.*—V. A., a 14-year-old Italian boy, stated that he lost his appetite a few days after he began taking sulfanilamide. The drug was discontinued and was resumed three months later. Again his appetite diminished, and he lost weight. Sulfanilamide was stopped.

2. *Anemia.*—A moderate decrease in the hemoglobin content was found in four cases, accompanied in only one instance by a drop in the red blood cell count. In the latter case, the hemoglobin value fell from 12 Gm. to 8.6 Gm., and the red blood cell count from 4 million to 3,200,000. Upon stopping the drug these values rose to their premedication level. Three months later, the same child was again given sulfanilamide, but this time there was no change in either the hemoglobin or the red blood cell value.

3. *Leucopenia.*—In six children the total white blood count dropped below 5,000, but in only two of these children did granulocytopenia (mild in degree) accompany the leucopenia. Therapy was continued in the four children who showed a leucopenia alone, and in all, the leucocyte count rose to normal levels. The leucopenia observed in these children was mild: between 4,000 and 5,000 in three children, and 3,700 in the fourth child.

Therapy was discontinued in the two children who showed leucopenia and granulocytopenia. In both cases the blood counts returned promptly to normal.

4. *Rash.*—A mild maculopapular eruption was observed on the arms and legs of one child, and on the face of another. Both eruptions disappeared soon after stopping the drug.

5. *Allergic Reaction.*—Finally, one child, a 13-year-old Italian girl, complained of a severe frontal headache, which came on three hours after the initial dose of sulfanilamide and which persisted for five days until she discontinued taking the drug. One month later, she was again given sulfanilamide, but this time she did not complain of headaches. After a week of medication, however, "swelling of both knees, elbows, and shoulders" appeared during one night, only to disappear the next morning. She continued taking the drug. Two days later, her face became swollen and remained so for forty-eight hours. Sulfanilamide was discontinued.

RESULTS OF TREATMENT

Evidence of rheumatic reactivation appeared in both the treated and the control groups. In the treated group of twenty-five children, three manifested rheumatic recrudescences, and two of them terminated fatally. The details of these three cases are as follows:

CASE 1.—J. C., a 13-year-old Italian boy, has been a patient in our clinic for several years and suffered from rheumatic involvement of both mitral and aortic valves. After five weeks of sulfanilamide medication, evidence of congestive failure appeared. The drug was stopped and the boy admitted to the hospital. He died one month after admission in congestive heart failure. Autopsy findings corroborated the clinical diagnosis of chronic rheumatic heart disease with recent reactivation.

CASE 2.—C. C., a 13-year-old Italian girl, had been attending the clinic for several years and presented evidence of mitral insufficiency and stenosis, and of aortic insufficiency. She was given sulfanilamide from September, 1939, through May, 1940, without any untoward effects and showed no evidence of active rheumatic heart disease throughout this period. In November, 1940, she began taking sulfanilamide again and continued doing so until the first week of February, 1941. At this time she complained of headache, chills, and fever. A suspicious petechia was seen on the hard palate. The child was referred to the hospital with the diagnosis of subacute bacterial endocarditis superimposed on rheumatic heart disease. Subsequent laboratory and clinical data confirmed the diagnosis. She died about four months after admission to the ward. No autopsy was obtained.

CASE 3.—The third child (A. F.), a 12-year-old Porto Rican boy, showed evidence of rheumatic activity within one month following cessation of sulfanilamide therapy. He had taken the drug from October, 1940, until the beginning of May, 1941. Three weeks later, the sedimentation rate was found to be elevated and an apical diastolic murmur which had not been heard for more than a year, reappeared.

Among the thirty children in the control group we found three patients with rheumatic reactivation, one of whom died of congestive heart failure.

CASE 1.—S. M., a 14-year-old Italian girl, had mitral insufficiency and stenosis. In August, 1941, she had a sore throat, which was followed shortly by pains in her knees, ankles, and back. These subsided after a few weeks, but recurred in October, 1941. There was, however, no change in either the sedimentation rate or the electrocardiogram.

CASE 2.—K. M., a 14-year-old Porto Rican girl, had rheumatic insufficiency and stenosis. In October, 1940, her sedimentation rate became elevated, and she complained of pains in both knees.

CASE 3.—A. Z., a 13-year-old Italian boy, had mitral insufficiency and stenosis. In February, 1940, evidence of congestive heart failure appeared. This became progressively worse, and he was referred to the hospital. He died March, 1940. No autopsy was obtained.

COMMENT

It is readily seen from the foregoing résumé of our results that we could not demonstrate any prophylactic effect of sulfanilamide in our group. Two deaths and one recrudescence occurred in the treated group; one death and two recrudescences in the control group. Since it is probable that congestive heart failure and subacute bacterial endocarditis in children with rheumatic heart disease indicate the presence of an underlying carditis, our results show therefore that episodes of active rheumatic heart disease occurred with equal frequency in both the treated and control groups.

Nevertheless, we cannot conclude from our study alone, that sulfanilamide has no effect whatever in preventing recurrences of active rheumatic heart disease. Our series is not large enough to be statistically convincing. Furthermore, the general incidence of rheumatic infection during our study period of from September, 1939, through May, 1941, proved to be exceptionally low. It is therefore possible that given a larger number of cases, treated during a time when rheumatic recrudescences were frequent, that the effect of sulfanilamide may have been apparent.

Thomas and her co-workers[3] found that "in no patient under treatment did this serious malady (subacute bacterial endocarditis) develop," and raised the question "of whether sulfanilamide may prevent this complication as well." The course of events in our patient C. C., who developed this complication while regularly taking sulfanilamide, indicates that the use of this drug to prevent subacute bacterial endocarditis leaves much to be desired.

SUMMARY

1. Sulfanilamide in daily doses of 20 grains (1.2 Gm.) was administered to twenty-five ambulatory rheumatic children ranging in age from 6 to 14 years. As controls, we observed thirty children with rheumatic heart disease who were attending the cardiac clinic but who were not given sulfanilamide.

2. Observations were started in September, 1939, and were carried through to May, 1940. They were resumed in September, 1940, and stopped in May, 1941. Two periods each, therefore, of approximately eight months each comprised the time of the study.

3. Minor toxic effects were noted. These consisted of: (1) anorexia, one case. (2) Moderate decrease in hemoglobin content in four cases, accompanied by a drop in red blood count in one of the children. (3) Moderate leucopenia in four patients with concomitant mild granulocytopenia in two of them. The blood counts returned promptly to normal in every instance upon withdrawal of the drug, and in a few cases even while the drug was continued. (4) Mild maculopapular eruption in two patients.

4. Two deaths (one from congestive heart failure, and another from subacute bacterial endocarditis) and one rheumatic recrudescence occurred in the

treated group. One death (from congestive heart failure) and two recrudescences occurred in the control group.

5. In our series of cases sulfanilamide did not appear to be of value in preventing rheumatic recrudescences.

CLINICAL CHEMISTRY

THE GLYCOLYTIC ENZYMES OF SYNOVIAL FLUID

ROGER S. HUBBARD, PH.D., AND RICHARD C. PORTER, BUFFALO, N. Y.

IN A previous publication[1] certain actions of glycolytic enzymes in cerebrospinal fluid obtained from patients with epidemic meningitis were discussed. Evidence was presented showing that while the larger part of the reducing sugar, glucose, in such spinal fluid disappears quite rapidly on incubation, the trace of fructose which is present[2] is destroyed very slowly. Other experiments showed that the enzyme which catalyzed the reaction was present in the cellular elements, and indirect evidence was presented which tended to prove that this enzyme was present in the polymorphonuclear leucocytes of the fluid. Further consideration of the question has shown that two objections can be made to these tentative conclusions. The first one is based on the nature of the material studied. The specimens in which the highest concentrations of leucocytes occurred were drawn shortly after acute exacerbations of the infection, and while tests designed to show the presence of meningococci gave negative results, still it is not impossible that organisms were present in small numbers and multiplied upon incubation of the specimens. Since meningococci react more readily with glucose than with fructose or, at least, form acid more readily from the first-named sugar,[4] the results cannot perhaps be attributed with certainty to the polymorphonuclear leucocytes. The second criticism is of an entirely different nature. Willstäter and Rhodewald,[5] in the course of investigations of the mode of formation of lactic acid from sugars, showed that, when buffered with phosphate solutions, glucose and fructose were about equally effective as sources for the formation of glycogen and lactic acid by suspensions of leucocytes.

Since these questions arose in connection with the earlier observations, it seemed desirable to carry out experiments in which (A) there should be available a convenient sterile source of large numbers of human polymorphonuclear leucocytes; (B) the sugars studied should be substances of known purity rather than those occurring in a complex biologic solution; and (C) the cells should be suspended in some biologic medium other than cerebrospinal fluid. In 1928 Cajori and Pemberton[6] described a patient with a sterile inflammatory reaction of the knee joint. On aspiration of this material it was found to be free from organisms but very rich in polymorphonuclear leucocytes. The authors carried out and reported the results of experiments upon the destruction of glucose added to this medium. Recently an opportunity presented itself of studying material from a similar case, and we decided to study the destruction of both glucose and fructose when added to this synovial fluid.

From the University of Buffalo, School of Medicine and the Edawrd J. Meyer Memorial Hospital.

Received for publication, Jan. 19, 1943.

The patient from whom the fluid was obtained was a Negro man 58 years of age. His chief complaint was that a swelling of the right knee was present and that he could move it only with difficulty. The knee was markedly swollen, not tender on palpation, and showed no sign of acute inflammation. The presence of fluid could be demonstrated on physical examination. Apart from this he had no complaints, and there were no other physical or laboratory findings which were abnormal. Serologic tests for gonorrhea and syphilis were negative. Material was repeatedly obtained from the joint space by aspiration. This synovial fluid was rich in protein and contained large amounts of mucin. It was apparently quite rich in fibrin, for in some instances a clot formed before studies could be initiated. Large numbers of leucocytes were present at all times, but the number varied quite markedly in different specimens. In at least one instance more than 1 c.c. of packed cells was obtained by centrifuging 10 c.c. of the fluid. Ninety per cent of the cellular elements were polymorphonuclear cells. The material was repeatedly examined for the presence of mircoorganisms. Tests were made, not only upon each of the six specimens used in the experiments to be discussed below, but also on at least six others. The methods of examination used included direct smears, cultures on many types of media, including those suitable for studying aerobic and anerobic organisms. Methods especially adapated for culturing the gonococcus and the tubercle bacillus were also employed. Specimens were also incubated for periods up to ninety-six hours and the incubated material later examined for organisms by direct smears and inoculation into various types of broth. Specimens of the fluid were also injected into guinea pigs. Positive results were not obtained by any of these methods in any instance. It seems certain that any demonstrable effects of cellular elements which might be found in studying this fluid were due to the leucocytes, for the number of organisms present must have been insignificant. The authors believe that the material was completely sterile.

In carrying out the experimental procedures, six different samples of this synovial fluid were used. The cell contents of these fluids varied markedly, but all were very high. In some studies the cells were first removed by centrifuging, and in others untreated fluid was used. These fluids were divided into portions of approximately 6 c.c. In many instances small amounts, usually 0.6 c.c., of concentrated sterile solutions of the purest glucose or fructose obtainable were added to these 6 c.c. portions and an equal amount of sterile water to an equal volume of the same material. These treated solutions were then mixed as thoroughly as possible to try to prepare equal concentrations of the cellular elements, and divided into three equal parts, each of which contained approximately 2 c.c. One of these was analyzed at once, one was placed in an incubator at 37° C., and the other placed in the icebox. An attempt was made to keep all solutions in each separate one of the six experiments identical, but this was found to be impossible because the leucocytes showed a marked tendency to clump together and because the gelatinous nature of the fluid, due to the presence of mucin, further prevented the preparation of suspensions of cells which were even approximately uniform. Even the three control preparations which made up integral parts of each separate test were not always exact duplicates of each other, although they seemed to show little variation in composition. The incubated and control solutions were precipitated by the zinc sulfate and sodium

hydroxide technique of Somogyi.[7] Reducing compounds were determined by the method of Folin and Wu[8, 9] and modified, when concentrations were low, according to the suggestions of Hubbard and Allison.[10] Fructose analyses were made by the resorcinol technique of Roe.[11] The solutions in which the determinations were finally carried out represented 1 to 10 dilutions of the original material. For the determination of concentration of sugar between 0.1 and 1.0 mg. per 100 c.c. (equivalent to concentrations of from 1 to 10 mg. per 100 c.c. of the original solutions), the method used for the determination of fructose was much more satisfactory than was the one used in determining reducing compounds. In each instance a culture was made of every solution upon which quantitative data were obtained, and all were found to be sterile.

The letters are given for reference to the text. Roman numerals show studies upon samples of fluid obtained by each of six separate punctures. Under "glucose" are given figures for total reducing compounds by the Folin and Wu method. Under "fructose" figures determined by the resorcinol reaction.

*Included in the averages listed under A.

The significant results obtained are given in Table I. In section A are given the average values for the studies in which sugars were added to the synovial fluid and the fluids incubated for forty-eight hours. Qualitatively the results of these experiments were all similar, and average values have therefore been presented. Quantitatively the results varied quite markedly. The most extreme variations encountered are given in sections B and C of the table. The average figures show that at least 90 per cent of the sugar originally present and 95 per cent of the glucose added were destroyed, while only between 70 and

75 per cent of the smaller amount of fructose added was lost on incubation. It seems probable that all the actual glucose present was destroyed in these experiments. The difference in the rate of destruction of these two sugars corresponds to the difference observed in the earlier experiments upon spinal fluid but is not as great as that found in those studies. The amount of the added fructose remaining in the solutions in the different experiments varied inversely as the concentrations of the cells present. The total reducing compounds reported as glucose, which were present after incubation, did not appear to be related to the cellular content. We believe that these figures largely represent nonglucose reducing compounds rather than glucose which had not been destroyed and that the irregularities noted are, in part, due to the difficulties inherent in determining such low concentrations of "sugar" and in part due to variations in the amount of some reducing compound extracted from the leucocytes in the different experiments.

Experiment B illustrates the difference in the destruction of these sugars when the solutions were incubated for periods of from twenty-four and forty-eight hours. The specimen studied in this instance was unusually rich in cells. Precautions were taken to try to insure the presence of equal suspensions of cells in all the solutions used, but it is probable that rather marked variations occurred. The added glucose was completely destroyed in twenty-four hours, while significant amounts of fructose, which was present initially in much lower concentration, were still found after forty-eight hours of incubation. The results obtained suggest that fructose was destroyed much more slowly during the second day of incubation than during the first one. This is true whether the figures are expressed in terms of the total amount of sugar or of the per cent of the total sugar which was present at the beginning of each twenty-four-hour period. Whether this apparent decrease in the rate of destruction was brought about by a decreased efficiency of the enzyme system, as some control experiments seemed to indicate, or resulted from a decrease in the amount of substrate, or from both cannot be determined.

Experiment C was designed to test the effect of variation in the amounts of the substrates upon the amounts of the sugars destroyed. In this instance varying amounts of the two sugars were added to a second specimen of fluid, which was much lower in cell content than was that used in Experiment B. In this experiment glucose in a concentration of 100 mg. per 100 c.c., or approximately a total of 2 mg. of sugar, was destroyed by the enzyme in 2 c.c. of fluid in forty-eight hours. Much smaller amounts of added fructose were destroyed. When 1.6 mg. of fructose (2 c.c. of an 80 mg. per 100 c.c. solution) were present, only 0.5 mg. was destroyed; when 0.8 mg. was present, only 0.08 mg. were destroyed. The difference between the reaction of the enzyme to the two sugars was striking, and in this experiment, as well as in the one just discussed (B) the amount of fructose removed appeared to decrease when the amount of sugar was decreased. In this instance also the difference in the rate of destruction was marked, whether it was expressed as amount of sugar or as per cent of the total amount of fructose initially present.

In Experiment D the addition of sugars to a sugar-free synovial fluid was studied. A specimen of fluid very rich in leucocytes (the same material used in experiment B) was incubated for twenty-four hours before the experiment was

begun. This experiment was the second one in which such a procedure was tried. In the earlier attempt all the glycolytic power toward both glucose and fructose disappeared when a speciman of fluid was incubated for one hundred hours. In this instance when sugars were added to the sugar-free fluid, 75 to 85 per cent of the 2 mg. of glucose and approximately 50 per cent of 1.8 mg. of fructose were destroyed in twenty-four hours. This experiment shows clearly that glucose was more rapidly destroyed than fructose when the sugars were added to incubated sugar-free synovial fluid. The destruction of fructose was approximately of the same magnitude as was that observed when fructose was added to the same untreated fluid (see results of Experiment B), but the destruction of glucose was apparently less marked than when the unincubated fluid was used. A number of factors affect the results which make us unwilling to draw definite conclusions from a comparison of these experiments. One of these is the difficulty in obtaining uniform cellular suspension. Another is the important part played in the calculations by the residual reducing compounds present at the time when the final analyses were made. It has already been pointed out that these varied markedly in different experiments, and in the present instance they appear to have been unusually high. Apart from such technical considerations, it is evident that two different effects may have been produced by the preliminary period of incubation. One is a destruction of the glucose originally present in the solution, so that in this instance the added fructose was the only sugar in the incubated material. The other is that the enzymes themselves may have been altered by the treatment, and this change in the enzyme may have had more effect upon the destruction of glucose than of fructose. Attempts were made to study this problem by modifying the conditions in various ways, but it was not found possible to determine definitely the cause of the difference between the results of Experiments B and D.

In Experiment E are given the results obtained by incubating synovial fluid from which cells had been removed by preliminary centrifugalization. In no experiment in which glucose or fructose was added to the cell-free fluid was there a significant change in concentration after incubation, and the average values only, therefore, have been included in Table I. The results of the experiments in which no sugar was added showed variations which were much greater than the probable accuracy of the methods employed, and the results of each have therefore been included. It is evident that not only were the average changes produced by incubation of the cell-free fluid smaller than those produced when cells were present, but also that in separate experiments the differences were marked. This seems to prove that the glycolytic enzymes affecting both glucose and fructose were present in the polymorphonuclear cells. However, two of a total of fourteen specimens (two of five specimens to which sugars were not added) showed a significant destruction of reducing compounds after forty-eight hours of incubation, and in one of these two instances, Experiment I. this destruction was marked. It seems most probable to us that in these two specimens enzymes had been extracted from the leucocytes, but the action of some other source of the glycolytic activity cannot be excluded. It should be noted that in the studies of Cajori and Pemberton[6] glycolytic activity of cell-free synovial fluid was demonstrated and that this activity was much less marked than was that of the uncentrifuged material.

In Experiment F are given results obtained when cells were removed from a speciman of fluid, washed in normal salt solution, and resuspended in the supernatant fluid. This experiment is interesting for a number of reasons. First, on the readdition of cells to a cell-free synovial fluid which possessed no glycolytic activity (as a control, see Experiment E IV, Table I), a distinctly demonstrable glycolytic activity was produced. Second, the destruction of glucose was more marked than was the destruction of fructose. Third, the process of centrifuging, washing and resuspending the cells had greatly reduced their enzymatic power, for the destruction of glucose and fructose was markedly less than the destruction in uncentrifuged material (see experiment C IV as control, Table I) although precautions were taken to have the concentration of the resuspended cells greater than that found in the original solution. In a second similar experiment carried out for forty-eight instead of ninety-six hours, no destruction of fructose and only a relatively slight destruction of glucose were observed.

Besides the experiments described above, cells from four of the six specimens, including those used in Experiment IV, were washed, resuspended in 0.85 per cent salt solution, and incubated for periods varying from forty-eight to ninety-six hours. No satisfactory evidence of a destruction of glucose or fructose added to such solutions was obtained in any of the experiments. This was probably due, in part, to the lessening of the enzymatic activity brought about by washing the cells illustrated by the experiments discussed in the preceding paragraph and in part by the unsuitability of the medium in which the cells were suspended. The suspensions to which no sugars were added did, however, give some fairly interesting results. When unincubated, sugar-free cellular suspensions were studied, no positive reducing or resorcinol reaction was obtained. After incubation the average "glucose" content of the four preparations was 12 mg. per 100 c.c., and the "fructose" concentration was 1.3 mg. per 100 c.c. The values in the specimens incubated ninety-six hours were higher than those studied after forty-eight hours. We believe that these apparent changes in the "sugar" content, which were almost certainly not due to glucose and fructose, were produced by disintegration of the cells. The same conclusion probably applies, we believe, to the small amounts of reducing compounds found in some of the experiments described in the earlier part of this paper.

It seemed possible that evidence might be obtained showing that glucose was changed into fructose or that fructose was converted into glucose; in other words, that a reaction simulating the Lobry de Bruyn effect[12] could be demonstrated during glycolysis by polymorphonuclear leucocytes. All specimens, both those containing glucose and fructose, as well as all control solutions, were therefore analyzed by both the reducing technique of Folin and Wu and the resorcinol technique of Roe. No evidence of the formation of one sugar from another was obtained. All variations of this type which were observed were of a magnitude which could be properly explained by the gradual increase in the control values found when suspensions of washed cells were incubated. Of course, the formation of small amounts of glucose from fructose under conditions which would lead almost immediately to their degradation would not be detected in such experiments.

CONCLUSIONS

When glucose or fructose was added to sterile synovial fluid which was rich in polymorphonuclear leucocytes, the sugars were destroyed. The rate of the destruction of glucose was at least twice as great as was that of fructose. The enzymes were present almost wholly in the cells, although they could occasionally be demonstrated in the cell-free fluid. The results confirm qualitatively those previously obtained upon cerebrospinal fluid.

The authors wish to express their gratitude to Mrs. Elfriedt Fendt Sicari for her technical assistance in the bacteriologic phases of this study.

STUDIES OF PANCREATIC FUNCTION*

II. The Effect of Injury to the Pancreas or the Liver Upon the Amylase and Lipidase Content of the Blood

Joseph H. Roe, Ph.D., and Norman P. Goldstein, M.A.
Washington, D. C.

QUESTIONS concerning the nature and origin of the lipidolytic enzymes of the blood are problems of major interest in physiology and clinical laboratory science. The earliest work of this kind was that of Hewlett[1] in 1904, who reported that after pancreatic injury there was in the urine an increase in the content of an enzyme which splits ethyl butyrate, or an "esterase"; also in one case there was observed in the urine an enzyme which splits the fats of olive oil, or a "lipase." Later, von Hess[2] (1912), also Hiruma[3] (1923), using

*From the Department of Biochemistry, School of Medicine, The George Washington University.
Received for publication, May 14, 1943.

ethyl butyrate as a substrate, obtained evidence indicating that there is an increase in the esterase content of blood after pancreatic duct ligation. In 1932 Cherry and Crandall[4] reported that after ligation of the pancreatic ducts in dogs, they could demonstrate in blood the presence of an olive oil-splitting enzyme (lipase), which normally did not appear in the blood stream. They also found that the activity of an enzyme normally present in blood, as measured by the hydrolysis of ethyl butyrate or tributyrin (esterase), did not show uniform increases after pancreatic duct ligation. They, therefore, concluded that the appearance in the blood of an enzyme which splits olive oil (lipase) is a specific indication of pancreatic injury.

Cherry and Crandall suggested that the term "lipase" be used to designate an enzyme which splits triglycerides of long chain fatty acids, as are in olive oil, and that the term "esterase" be used for an enzyme which splits simple esters, such as ethyl butyrate. They found, however, that tributyrin is apparently split by the same enzyme that hydrolyzes ethyl butyrate.

In 1934 Comfort and Osterberg,[5] using the Cherry and Crandall method for estimating serum lipase, reported elevated values for serum lipase in 95 per cent of cases of active pancreatitis, in 36.5 per cent of cases of carcinoma of the pancreas, and in 60 per cent of cases of carcinoma of the ampulla of Vater. In a later paper[6] these authors reported essentially the same results with this test, but in addition they found an increased serum lipase content in 97 per cent of cases of disease of the biliary tract in which there was an associated pancreatitis. These authors stress the requirement that the test must be made in less than ten days after the onset of pain. They conclude that the serum lipase determination is an efficient test for active pancreatitis, but less so for malignant disease of the pancreas.

In another paper[7] we have reported a procedure which includes greatly improved conditions for the determination of the lipidolytic enzymes of blood serum. With this method we have carried out an investigation in which conditions were set up to study the origin of these enzymes and their possible relation to pancreatic disease. Variations in the lipidolytic enzymes of the blood were followed with our method using five different substrates. Since Elman,[8] and others, have found the blood amylase a useful determination in acute pancreatic disease, it was decided to make parallel determinations of the serum amylase along with the lipidase estimations. For the amylase determination we used the method of Somogyi.[9] The cat was used as the experimental animal.

Four general types of experiments were set up. These were a study of the effect of the following upon the content of amylase and lipidolytic enzymes in the blood: (1) eserine and mecholyl stimulation; (2) ligation of the pancreatic ducts plus eserine and mecholyl stimulation; (3) pancreatectomy; (4) liver poisoning by chloroform. We were particularly interested in finding what conditions will elevate the blood concentration of these enzymes; whether, or not, these enzymes have an origin other than in the pancreas. Also, by means of the five substrates used, we hoped to obtain data showing which substrate could be considered the most reliable for studying pancreatic disease. A discussion of the experimental techniques and results is given.

ESERINE AND MECHOLYL STIMULATION

Experiments with eserine and mecholyl were carried out to standardize a method for stimulating pancreatic secretion which could be used for further experimentation. The procedure adopted was as follows: Cats were anesthetized by injecting intraperitoneally 30 mg. of nembutal per kilo of body weight. After anesthesia had developed, a control sample of about 18 c.c. of blood was collected by heart puncture. Eserine sulfate and mecholyl were then injected subcutaneously. A single dose of eserine sulfate, ranging from 0.125 to 0.50 mg., was administered, and the dosage of mecholyl was 0.05 mg. per kilo of body weight injected every half hour. After three to four hours of mecholyl administration a second sample of 18 c.c. of blood was collected from the heart.

Large samples of blood were collected to be able to carry out tests on five substrates for the lipidolytic enzymes, and also to carry out an amylase test. Since large blood samples had to be taken, it was obvious that only two samples of 18 c.c. each should be studied with an animal the size of the cat to obtain valid data; otherwise the blood analyses might reflect the result of hemorrhage. Therefore, in most of the data of this report only two blood samples were analyzed, the control and the experimental collected at the end of the experiment.

In Table I are the results of mecholyl stimulation in the presence of inhibition of acetyl choline esterase action by eserine. In practically every group of comparative analyses there is an increase in the amount of amylase and lipidolytic enzymes in the blood serum. A control on this experiment would be useful as some blood volume changes might take place as a result of the initial bleeding, the salivation, or other losses of fluids. The nearest to a control that could be obtained is the experiment with Cat 21, a depancreatized animal that had been healed with insulin. The increases observed in this cat are 12 per cent with tributyrin as substrate, 10 per cent with triolein, and 14 per cent with olive oil, values which are within the limits of error of this method. In view of these results with a depancreatized animal, it appears that the increases in blood enzymes observed after eserine and mecholyl stimulation of the intact animals are significant and that they reflect principally a pancreatic response. The increases in the lipidolytic enzymes noted are essentially parallel with the different substrates; hence no differentiation in these enzymes could be made. It is also of interest that the increases in amylase and lipidase are of the same magnitude.

PANCREATIC DUCT LIGATION WITH MECHOLYL STIMULATION

The results of experiments with pancreatic duct ligation are shown in Table II. In these experiments cats were anesthetized with nembutal and a control sample of blood was taken from the heart. A laparotomy was performed, and the pancreatic ducts were doubly ligated and cut between the ligations. Care was taken to ligate all ducts from the pancreas and not to obstruct the bile ducts. The abdomen was closed with sutures and skin clamps. Eserine and mecholyl were administered as described above. After two to five hours of mecholyl administration samples of blood were collected. All bloods were analyzed for amylase and for lipidolytic enzymes with five substrates.

Values are expressed in units per 100 c.c. of Serum. For amylase the Somogyi unit was used. The lipidolytic unit has been defined in another paper.[7]

This experiment was done to simulate conditions that probably exist in an active pancreatitis where obstruction occurs. A marked increase in amylase and lipidase was observed. The increases in amylase and lipidase are of essentially the same magnitude. These experiments show that pancreatic enzymes readily pass into the blood stream when the flow of external secretion of the pancrease into the duodenum is blocked. They do not indicate any difference in sensitivity of response of amylase as compared with lipidase. With the five substrates for lipidolytic enzymes, the order of sensitivity of response was the same as in normal cat serum. Tributyrin was split most rapidly; benzyl butyrate was next; and ethyl butyrate, olive oil, and triolein were the least sensitive to the splitting action of the enzymes present. Thus, a differentiation in the lipidolytic enzymes that appear in the blood serum after pancreatic duct ligation is not shown by these experiments.

THE EFFECT OF PANCREATECTOMY

The origin of the amylase and lipidase of the blood is a question of considerable importance. Somogyi[9] has presented convincing evidence that amylase is produced by the liver and it is well known that amylase is secreted by the salivary glands. The effect of pancreatectomy on the serum amylolytic potency has been investigated by a number of laboratories.[10-13] Reports upon this work are in good agreement in regard to a sharp postoperative drop in serum amylase concentration, but there are conflicting results as to whether or not the serum amylase value returns to normal with control of the diabetes by insulin. In as far as we know, the effect of pancreatectomy upon the concentration of lipidolytic enzymes in the blood has not been reported. We, therefore, decided that a study of the concentration of serum lipidase and amylase in cats following pancreatectomy would be of interest.

Pancreatectomy was performed under nembutal anesthesia, and the diabetes was controlled by insulin administration. The data obtained in these experiments are shown in Table III. The results in the experiment with Cat 27, in which blood was collected twenty-four hours after pancreatectomy, do not show variations that could be considered outside the limits of experimental error. Considering the other experiments as a group, the data show a decrease in the values for amylase and lipidolytic enzymes, following pancreatectomy, with a mixed return trend toward preoperative levels. No conclusion seems warranted from these results other than the very definite observation that amylase and lipidolytic enzymes do not disappear from the blood serum after pancreatectomy. This observation is in agreement with other work regarding the effect of pancreatectomy on the amylase content of serum and it appears to be a new finding concerning the lipidolytic enzymes of the blood.

The results of these studies, together with those of Table II, lead to the conclusion that the lipidolytic enzymes of the blood have an extrapancreatic as well as a pancreatic origin.

CHLOROFORM POISONING

It has been reported by several laboratories[4, 14, 15] that the liver does not produce an enzyme which splits the lipids of olive oil. We have obtained in-

TABLE IV

THE EFFECT OF CHLOROFORM POISONING ON THE CONTENT OF AMYLASE AND LIPIDOLYTIC ENZYMES OF THE BLOOD OF THE CAT

CAT NO.	HOURS AFTER INJECTION OF CHLOROFORM BLOOD SAMPLE WAS COLLECTED	SUBSTRATE											
		STARCH		TRIBUTYRIN		ETHYL BUTYRATE		BENZYL BUTYRATE		TRIOLEIN		OLIVE OIL	
		CONTROL	EXPERIMENTAL	CONTROL	EXPERIMENTAL	CONTROL	EXPERIMENTAL	CONTROL	EXPERIMENTAL	CONTROL	EXPERIMENTAL	CONTROL	EXPERIMENTAL
17	18	1179	533	93	153	54	102	79	144			31	29
21	20	710	428	150	243	108	257	101	217	50	38	45	31

Dosage: 1 c.c. U.S.P. Chloroform per kg. of body weight. Values are expressed in units per 100 c.c. of serum. For amylase the Somogyi unit was used. The lipidolytic unit used has been defined in another paper.[7]

formation in agreement with this finding: a glycerol extract of liver was found to split ethyl butyrate, benzyl butyrate, and tributyrin, but not olive oil. In view of these findings, it was believed desirable to carry out liver poisoning experiments which might offer suggestions upon the influence of the liver, when diseased, upon the concentration of lipidolytic enzymes in the blood. The use of chloroform seemed indicated, since this compound has a primary toxic effect upon the liver.

In these experiments cats were anesthetized with nembutal, and control samples of blood were collected from the heart. Chloroform dissolved in olive oil was injected subcutaneously, the dosage being 1 c.c. of U.S.P. reagent per kilo of body weight. Samples of blood were collected at times varying from eighteen to forty-two hours after injection of chloroform. All bloods were analyzed for amylase and for lipidolytic enzymes by five substrates.

The results are shown in Table IV. The serum amylase decreased in all cases. The triolein and olive oil-splitting enzymes showed a very slight decrease, the significance of which is uncertain. A marked increase in the enzyme, or enzymes, of serum which split tributyrin, ethyl butyrate, and benzyl butyrate occurred. These results are of considerable interest because they show a differentiation in the lipidolytic enzymes of the blood; in an experimental procedure upon the intact animal, the enzyme, or enzymes, which split esters and tributyrin (esterase), were found to be increased in the blood serum, while the enzyme, or enzymes, which split triolein and the lipids of olive oil (lipase), remained at approximately the same or a slightly lower level. This is good evidence in favor of the assumption that there are in the blood two lipidolytic enzymes, or groups of enzymes: namely, esterases, which split simple esters and short chain fatty acid triglycerides, and lipases which hydrolyze triglycerides.

The most obvious conclusion concerning the increase in the esterase activity of the serum in chloroform poisoning is that it is a response to liver damage, although chloroform may have a toxic effect upon other organs or tissues which would be reflected by changes in the enzyme concentration of the blood. More work upon this phase of the problem should lead to interesting results.

DISCUSSION

The experiments described above were designed to get information upon the origin of the amylolytic and lipidolytic enzymes of the blood, and to study the relation of the pancreas and the liver to the circulating level of these enzymes in the blood. It was also thought that the use of five substrates for the estimation of the lipidolytic enzymes might yield evidence concerning the identity of these enzymes.

Stimulation with mecholyl in the presence of eserine, with and without pancreatic duct ligation, caused marked increases in the amylolytic and lipidolytic enzymes of the blood of cats. The increases in amylase and in lipidase were of the same magnitude, and there was no essential difference in the responses measured by the five different substrates for the lipidolytic enzymes. These results demonstrated that there is an increase in enzymes of pancreatic origin in the blood when a strong vagal stimulus is applied and when pancreatic duct occlusion occurs.

Pancreatectomy experiments resulted in some decrease in amylase and lipidolytic enzymes in the serum with irregular return trends toward normal levels. These experiments showed that both the "esterase" and "lipase" types of enzymes in the blood of the cat have an extrapancreatic source in addition to their pancreatic origin.

Experiments in which cats were poisoned with chloroform showed a decrease in serum amylase and a very slight decrease in the enzyme, or enzymes, of the serum which split triolein and the lipids of olive oil. Sera from the same animals, however, showed an increase in the enzymes which split tributyrin, ethyl butyrate, and benzyl butyrate. These experiments gave data which indicate a clear differentiation between the so-called "esterase" and "lipase" of the blood serum. Since chloroform has a primary toxic effect upon the liver, these results raise the question of whether or not the "lipase" determination, published by ourselves and others, might reflect the presence of liver disease as well as pancreatic injury. This question may be answered only by clinical studies.

SUMMARY

1. Experiments upon cats have been carried out which were designed to obtain information upon the origin and identity of the lipidolytic enzymes of blood serum.

2. Stimulation with mecholyl in the presence of eserine, with and without pancreatic duct ligation, caused marked increases in the concentrations of amylolytic and lipidolytic enzymes in the blood.

3. Pancreatectomy resulted in postoperative decreases in serum amylase and lipidase, with mixed return trends toward normal levels. These experiments demonstrated that the amylolytic and lipidolytic enzymes of the blood have an extrapancreatic source in addition to their pancreatic origin.

4. Chloroform poisoning caused a decrease in serum amylase. With respect to the lipidolytic enzymes of the serum, a dissociation of effects was observed: The triolein and olive oil-splitting enzymes showed a very slight decrease; and the enzyme, or enzymes, which split ethyl butyrate, benzyl butyrate, and tributyrin, were definitely increased. The latter behavior is evidence in favor of the existence of both "esterase" and "lipase" in blood serum.

INTRAVENOUS INJECTIONS OF SOLUBLE TIN COMPOUNDS*

Joseph Seifter, M.D., and Edward S. Rambousek, M.D.†
Cleveland, Ohio

THERE are no complete studies of the distribution of tin in the organs following intravenous injection of tin compounds. Accordingly, we adapted for toxicologic study the toluene 3,4-dithiol method developed by Clark[1] and extended to canned foods by DeGiacomi.[2] We also found it necessary to prepare tin compounds suitable for intravenous injection. The results of these studies are reported in this paper.

METHOD OF DETERMINING TIN

Preparation and Storage of Toluene-3-4-dithiol.—We obtained the compound, which is not on the market, by first preparing sizable batches of sodium toluene-3,4-disulfonate (3) and, then as the occasion arose, by converting small amounts of this to the dithiol (3). The distilled product was stored in a dark refrigerator.

Dithiol Solution.—A 0.2 per cent solution of dithiol in 1 per cent aqueous NaOH containing 0.5 per cent thioglycollic acid remains clear for several days when kept in the refrigerator. The solution should be discarded when turbidity appears.

Standard Sn Solutions.—Reagent grade tin metal is dissolved in concentrated HCl containing 0.5 per cent thioglycollic acid so that 1 c.c. represents 1 mg. Sn. This stock solution keeps indefinitely. For use in the analytic procedure, the stock solution is diluted with 0.5 per cent thioglycollic acid in dis-

Aided by a grant from the Therapeutic Research Committee of the Council on Pharmacy and Chemistry of the American Medical Association. A preliminary communication was presented to the Society for Experimental Biology and Medicine, Cleveland, Ohio, November 12, 1941.

Received for publication, May 4, 1943.

tilled water so that 1 c.c. represents 0.01 mg. Sn. This solution should be prepared fresh each day.

Range of Color.—In the range of 2 gamma to 20 gamma Sn there is a progressive increase in color, and the unaided eye readily detects differences of 3 gamma. In our experiments this sensitivity is 5 times greater than with the molybdenum-blue method.[4]

Procedure.—Fresh tissue (5 to 100 Gm.) is dissolved in a minimum of concentrated HNO_3, evaporated to dryness, and placed in a muffle oven at 500 degrees Centigrade until the charred organic matter is removed (usually twelve to sixteen hours). The ash is brought to fuming with 5 c.c. concentrated H_2SO_4, and heating is continued until solution takes place. After cooling, the mixture is neutralized with NH_4OH, acidified with HCl, diluted to 100 c.c. with distilled water, and finally brought to proper acidity by adding 2 c.c. of concentrated HCl. Hydrogen sulfide is passed through the mixture for 1½ hours, and the precipitate is collected on a Gooch crucible. The precipitating flask is rinsed with 30 c.c. of 10 per cent aqueous NaOH followed by distilled water. Each rinse is passed through the crucible. HCl is permitted to seep through until the filtrate is acid to litmus; then distilled water is passed through. The final volume is adjusted by evaporation or dilution to contain not less than 0.5 gamma nor more than 100 gamma Sn per c.c. To an aliquot of 5 to 10 c.c. in a tube there are added 1 drop of thioglycollic acid, 0.5 c.c. concentrated HCl, and 0.5 c.c. of dithiol reagent. A like amount of tin standard solution is treated in the same fashion. Both tubes are immersed in boiling water for ten seconds and the colors are compared directly by light reflected from a white background. The red color is discharged by various organic solvents (i-amyl acetate, i-amyl alcohol, n-butyl alcohol, di-n-butyl ether, carbon disulfide).

Factors Influencing Amount of Sn Recovered.—1. *Muffle Heating* for twelve to sixteen hours at 500 degrees Centigrade in the presence of H_2SO_4 or NaOH did not result in loss of Sn. The presence of HNO_3 resulted in lower values which were restored to practically complete recovery by heating the ash with concentrated H_2SO_4 to fuming, then neutralizing with alkali, and finally acidifying with HCl. The recoveries were made on duplicate samples in the range of 5 gamma to 100 gamma Sn.

2. *Sulfide Precipitation* resulted in a loss of Sn. With 50 gamma to 1 mg. the recovery was 96 to 100 per cent; at 10 gamma the recovery was 80 to 90 per cent; at 5 gamma it was 60 to 70 per cent.

3. *Presence of Animal Tissue* accounted for still greater loss of Sn in the lower ranges. With 100 gamma to 2 mg. the recovery was practically complete; with 50 gamma it was 90 to 94 per cent; with 5 to 30 gamma it was 60 to 80 per cent. Consequently the method has only qualitative significance if the sample contains 50 gamma or less and is doubtful at 5 gamma.

PREPARATION OF TIN COMPOUNDS

Stannic Citric Acid was prepared by adding 5 c.c. stannic chloride (anhydrous) to 30 Gm. of sodium citrate .11 H_2O dissolved in 40 c.c. of distilled water. The reaction product was precipitated by the addition of 10 volumes of 95 per cent ethyl alcohol. In one hour this was filtered and the white precipitate repeatedly washed with 95 per cent alcohol. Analysis by the dithiol method gave 20 per cent Sn. The product formed aqueous solutions readily

from which the sulfide was precipitated very slowly with H_2S. The aqueous solution (12.5 per cent) was acidic and 1 c.c. required 5.72 c.c. of N/10 NaOH for neutralization. For injection only neutralized solutions were used.

Stannous Citric Acid (20 per cent Sn), prepared with stannous chloride and precipitated as just described, flocculated when neutralized. Consequently the acid form was injected.

INTRAVENOUS INJECTION IN RABBITS

Stannic and stannous citric acids were injected instead of tin salts since the latter are liable to produce colloidoclastic shock. Neither compound in solution flocculated with rabbit serum, 10 per cent egg white solution, nor with Ringer's solution at pH 6.0, 7.0, or 8.5. Neither did they hemolyze mammalian erythrocytes.

Death usually occurred during intravenous injection of solutions of either compound in about twenty minutes; when approximately 500 mg. (100 mg. Sn) per kg. had been introduced at the rate of 0.5 c.c. per minute. Tremors appeared when 25 per cent of the fatal dose had been administered; flaccid paralysis when 50 to 60 per cent had been administered; and terminal tonic and clonic convulsions toward the end of the injection. The viscera, especially the lungs, were severely congested. The acutely fatal dose is practically the same as for sodium citrate. Animals which received only 50 per cent of the acutely fatal dose responded with a brief period of excitement followed by lethargy, from which they recovered and showed no further symptoms until death four days later. At autopsy the kidneys were pale and granular. No edema was seen. Animals which received 25 per cent or less of the acutely fatal dose survived until sacrificed about one month later.

ORGAN CONCENTRATION AND FATE OF THE INJECTED TIN

Our data in Table I are too few to warrant detailed deductions but point to the similarity of tin to heavy metals,[4, 5] especially bismuth. In general the amounts of Sn in the kidneys, and lungs, the intestines, and the bile diminished progressively with the time after injection; but those in the livers, and the spleens increased before they decreased. Animals that died during injection, or shortly after, had Sn in all organs and fluids that were examined; but after three weeks only spleen, liver, and kidney had amounts sufficient for analysis. The kidney probably loses the metal last. The kidneys, except in Rabbit 1, had a considerably greater concentration of metal than did other organs. The concentrations in the intestines and the bile did not exceed those of the urine. The spiral valves of the intestines were not involved in detoxification since they did not have high tin concentrations and had no deposit of tin sulfide.

CONCLUSIONS

1. Dithiol is applicable for quantitative analysis of tin in tissues.

2. The method is quantitative for samples containing at least 50 gamma of tin.

3. The sojourn and concentration of tin resemble heavy metals, especially bismuth.

4. The organs tolerate relatively high concentrations of tin.

5. Tin is excreted rapidly following intravenous injection.
6. Stannic citric acid and stannous citric acid possess low toxicity.

LABORATORY METHODS

GENERAL

DEMONSTRATION OF TUBERCLE BACILLI IN TISSUE BY FLUORESCENCE MICROSCOPY*

GERMAIN CROSSMON, B.S., AND ERICH LOEWENSTEIN, PH.D., ROCHESTER, N. Y.

AT THE present time there is much interest in the identification of *Mycobacterium tuberculosis* in smears of pus, sputum, and body fluids by staining with a fluorescent basic dye, auramine O, and examination of preparations in ultraviolet illumination. The staining procedure is similar to the Ziehl-Neelsen method with the substitution of the fluorescent dye, auramine, for basic fuchsin. Thin smears are stained with carbolauramine usually at room temperature. The preparations are decolorized with acid alcohol, washed with water, and examined dry without a cover glass by means of the fluorescence microscope in ultraviolet light. Hagemann[1] in 1938 introduced this method. Since this publication, a number of papers[2, 3, 4, 5, 6, 7, 8, 9, 10] have been written confirming his results. These authors consider this method superior to the Ziehl-Neelsen technique for the detection of the tubercle bacillus in smears of sputum, pus, and body fluids for the following reasons:

1. The staining method with auramine is simpler than with basic fuchsin (Ziehl-Neelsen). Smears can be stained with carbolauramine at room temperature, while steaming carbolfuchsin is usually necessary for the Ziehl-Neelsen method.

2. Auramine, a di-phenyl methane basic dye, is probably a more specific stain than basic fuchsin for acid-fast organisms. (The number of tubercle bacilli stainable with carbolauramine appears to be greater than with carbolfuchsin.)

3. More tubercle bacilli are detected in smears stained with carbolauramine than with carbolfuchsin. Self-luminous, yellow fluorescent tubercle bacilli stained with the fluorescent dye, auramine, are more easily seen against a dark background than red-stained bacilli on a blue background. Bogen[6] reports in 1,000 duplicate smears stained in parallel by the Ziehl-Neelsen and fluorescent methods, there were over 20 per cent more positive tests by the newer technique.

*From the Medical Department and Scientific Bureau of Bausch & Lomb Optical Co.
Received for publication, December 3, 1942.

Lind and Shaughnessy[9] in an examination of 1,123 smears by means of the Ziehl-Neelsen and fluorescence methods found 106 to be positive. Twelve of these preparations, positive by the fluorescence method, were negative by the Ziehl-Neelsen method. They also state that because of the larger areas covered and ease of examination, the time required was reduced to one-fourth or one-third that required for the Ziehl-Neelsen method.

4. Smears are examined for tubercle bacilli in much less time. An oil immersion objective with a 10X eyepiece provides the usual magnification (930X) for examination of smears stained by the Ziehl-Neelsen method. Tubercle bacilli stained with auramine appear as yellow, fluorescent bodies on a dark field. The fact that the bacilli become secondary light sources serves to increase the contrast. Therefore lower magnification may be used, and thus a larger field may be examined at one time.

The fluorescence staining method as used for smears of sputum, pus, and body fluids may be modified for the detection of *Mycobacterium tuberculosis* in fixed tissue. The staining technique, equipment, and method of examination are as follows:

STAINING METHOD

1. Fix tissue in 10 per cent neutral formalin for twelve to twenty-four hours. Commercial formalin may be neutralized by the addition of marble chips a few days prior to fixation.

2. Dehydrate completely, imbed in paraffin and cut sections on a microtome at 6 to 10 microns. After removal of paraffin with xylol and passage through alcohol to water, place sections in carbolauramine. Since paraffin will fluoresce, it is essential that it be entirely removed by xylol.

Auramine O (National Aniline)	0.1 Gm.
Distilled water	100 c.c.
Liquefied phenol U.S.P.	4 c.c.

The auramine O is dissolved in the distilled water by shaking strongly in a flask. Gentle heating will hasten its solution. When the auramine is dissolved, the liquid phenol is added.

The application of heat shortens the staining time and usually increases the intensity of the stain. The following staining times are suggested:

Room temperature	30 minutes
Incubator 37° C.	15 minutes
Paraffin oven 55° C.	10 minutes
Gentle steaming of slides flooded with carbolauramine	3 to 5 minutes

4. Wash the preparations briefly in several changes of distilled water.

5. Decolorize in 95 per cent ethyl alcohol containing 0.5 to 1 per cent hydrochloric acid until the preparations are quite colorless. The time for decolorization does not usually require more than forty-five seconds. Two to three changes of acid alcohol should be used for this decolorization.

6. Wash preparations in distilled water.

7. Transfer to 0.1 per cent aqueous methylene blue, certification No. 18 (National Aniline), C. I. No. 922. Sections are stained from thirty seconds to one minute. As with the Ziehl-Neelsen method, the methylene blue removes any carbolauramine not removed by the acid alcohol with little sacrifice of the intensity of the auramine in the tubercle bacilli. In addition, by staining the tissue the methylene blue masks the natural fluorescence of the tissue and forms a dark background for the yellow, luminous tubercle bacilli.

8. Rinse in distilled water.

9. Dehydrate, clear in xylol, and mount in xylol-clarite. Most mounting media, including balsam, fluoresce in ultraviolet light. Tissue preparations are usually examined dry without a cover glass or mounted in nonfluorescing media such as distilled water, glycerin, or medicinal mineral oil. Although xylol-clarite fluoresces slightly, preparations mounted in this medium are permanent. In addition, its refractive index 1.515 is more favorable for the examination of stained elements.

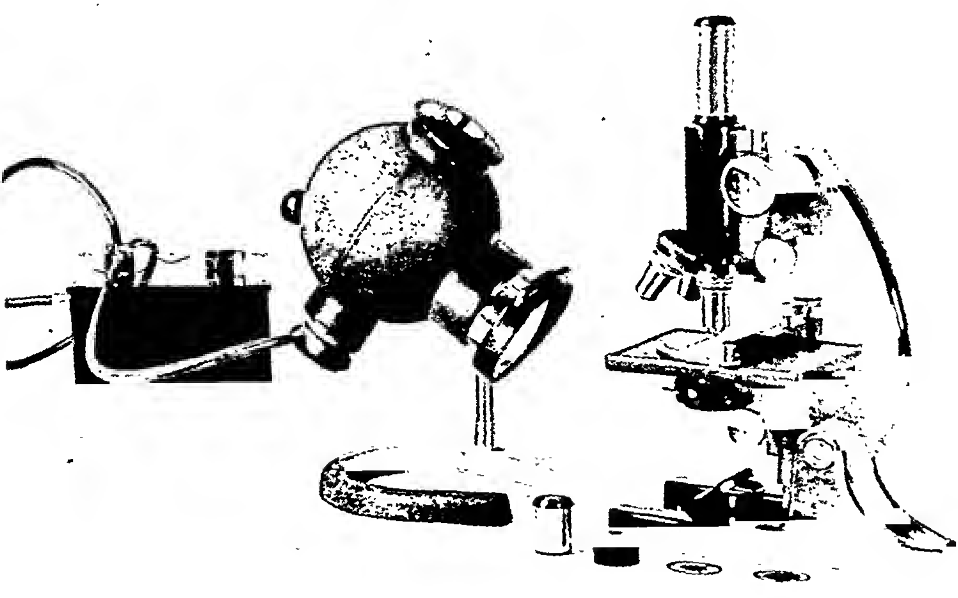

Fig. 1.—Equipment for fluorescence microscopy. Mercury vapor lamp, ultraviolet transmitting filter, Abbe Condenser 1.25 N.A., dark field stop 15 mm. diameter.

Any microscope (see Fig. 1) having a magnification of 430X and suitable for the examination of biologic material can be used for this work. The standard medical microscope is suggested. Although not absolutely necessary, the ordinary silvered glass mirror should be replaced with an aluminized mirror, for both glass and silver absorb ultraviolet.

As a source of illumination a mercury vapor lamp with iris diaphragm and filter holder is suggested. An ultraviolet transmitting glass filter and a dark field stop complete the equipment necessary for examination.

METHOD OF EXAMINATION

The preparations are best examined by enclosing three sides of the microscope with a shield to exclude extraneous light. A drop of nonfluorescent sandalwood oil or Shillaber's Immersion Oil is placed between the slide and condenser. The beam of light from the mercury vapor lamp is centered on the microscope mirror, and the condenser is focused up and down until a uniform distribution of light is obtained in the microscope field. The best condition is obtained when the substage condenser forms an image of the front aperture of the lamp in the plane of the specimen. A dark field stop is placed in the slotted ring below the substage condenser. Low power magnification with 5X or 10X eyepiece and 16 mm. objective is usually employed for the initial exploration. The observer should search for any luminous yellow bodies on a

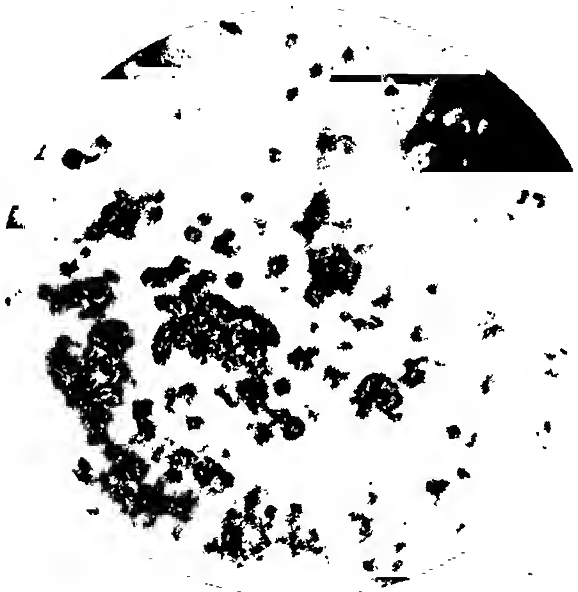

Fig. 2.—Photomicrograph of tubercle bacilli in lung tissue. Apochromatic objective 8.3 mm., 0.65 N.A. Eyepiece 10X Hyperplane. Magnification 400X. Exposure time: 7½ minutes.

dark field. Provided the staining technique has been properly employed, the only luminous structures in the field will be tubercle bacilli. A higher magnification, 5X or 10X eyepiece with 4 mm. objective, should now be used to inspect the morphology more closely. Tubercle bacilli appear as thin, yellow, luminous, slightly curved rods on a dark background. (See Figs. 2 and 3.)

Variations in the method of examination will be suggested to the observer. For example, one may prefer to use an 8 mm. objective with a 20X ocular, or for higher magnifications, a 15X or 20X eyepiece with the 16 mm. or 4 mm. objective. Although an oil immersion objective is not necessary, it may be used even in an undarkened room with a 5X or 10X ocular using Shillaber's immersion oil, sandalwood oil, or synthetic oil of wintergreen between the slide and objective. If desired, preparations may be first focused and examined in visible

light by using a daylight filter or a ground glass and blue filter. This will show the nuclei of the tissue cells and other basophilic elements that may be present, stained blue by the methylene blue. In the case of smears of sputum, pus, and body fluids, the blue staining of the nuclei of leucocytes can be observed. If many tubercle bacilli in the preparation are concentrated at one spot, it is even possible at this time by partially closing the diaphragm and using a high dry 4 mm. objective to locate this auramine-stained area in visible light. It appears as a pale yellow area on the methylene blue background. According to Gage,[11] a long card smeared with anthracene in a strong solution of cane sugar and dried makes a good detector for focusing the beam upon the aluminized mirror, and a similar preparation on a corex glass slip serves well for making sure that the ultraviolet is passing up through the condenser to the place where the preparation is to be located. A piece of fluorescent glass or cellophane might be used just as well for the same purpose.

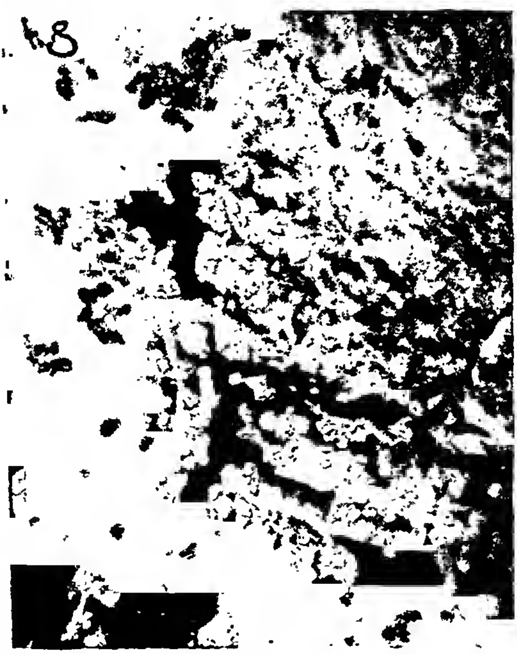

Fig. 3.—Photomicrograph of tubercle bacilli in lung tissue. Achromatic objective 4 mm., 0.65 N.A. Eyepiece 7½ Hyperplane. Magnification 400×. Exposure time: 30 minutes.

Distilled water or glycerin does not fluoresce, and although their refractive index is not that of immersion oil, they can be used in place of sandalwood oil or Shillaber's Immersion oil to make contact between the slide and condenser.

SUMMARY

A staining method and equipment* for the detection of tubercle bacilli in tissue is described. Tissue sections 6 to 10 microns are stained with carbol-auramine solution and decolorized with acid alcohol. Preparations are counterstained with methylene blue, dehydrated, cleared, and mounted in xylol-clarite

*The equipment, including mercury vapor lamp, dark field stop, filter, metal shield, and aluminized mirror may be obtained from Bausch & Lomb Optical Co., Rochester, N. Y.

for permanent preparations. Distilled water, glycerin, medicinal mineral oil, or Shillaber's Immersion oil may also be used as mounting medium, provided the cover glass is sealed with shellac or paraffin wax. The preparations are examined with ultraviolet radiation using low power magnification (50X or 100X) and a dark field stop for the initial examination. Higher magnification (430X) is necessary to check the morphology of stained elements. Tubercle bacilli appear as thin, yellow, luminous, slightly curved rods on a dark background.

The staining method and fluorescence microscope have also proved satisfactory for the detection of *Mycobacterium tuberculosis* in sputum, pus, and body fluids. One of us, Erich Loewenstein, has successfully used this method for the detection of lepra bacilli in smears.

We acknowledge with thanks the assistance of Mr. J. V. Butterfield of the Scientific Bureau of Bausch & Lomb for making the photomicrographs shown in this paper.

AN IMPROVEMENT OF THE SEROLOGIC KAHN REACTION IN THE SPINAL FLUID*

F. RAPPAPORT, PH.D., AND D. RAPPAPORT, PH.D., PETAH TIQVA, PALESTINE

THE Kahn test is carried out with ease and gives very reliable results in serum. In spinal fluid, however, various difficulties arise, so that other methods have been preferred. These difficulties result mainly from the attempt to concentrate the effective antibodies through precipitation with ammonium sulfate, as recommended by Kahn himself. In this method, the spinal fluid is mixed with an equal quantity of a saturated solution of ammonium sulfate and well shaken, thus precipitating the globulins. Inactivation is obtained by heating the mixture at 56° C. for twenty minutes. It is then centrifugated at high speed and the supernatant fluid is poured off.

The following factors may lead to inaccuracies:

1. A certain quantity of antibodies may be dissolved in the supernatant sulfate solution, and when the latter is poured off, they are lost for the reaction.

2. The spinal fluid may be poor in globulins, so that, although it may be rich in antibodies, only a fraction of them is precipitated together with the present amount of globulins.

3. The salt concentration should always be the same and should be reproduced exactly. The considerable quantity of ammonium sulfate which may remain in the precipitate obviously changes the salt concentration in which the reaction is going to take place.

4. Finally, the scarcity of albumin in the spinal fluid may lead to a pseudopositive reaction, for the flocks of the antigen which are normally dissolved in serum may remain suspended in a fluid poor in albumin.

Considering that the inaccuracies mainly arise from the attempt to concentrate the antibodies in the spinal fluid, we developed a method for spinal fluid, similar to the one used for serum.

Reagents employed:

I. a. Kahn antigen
   b. 0.9 per cent NaCl solution
II. A reliable nonluetic serum (Kahn negative)

The antigen is thoroughly mixed with the salt solution to the given titer and left to ripen for at least ten minutes at room temperature.

PROCEDURE

Pour 0.1 c.c. of serum (reagent II) in each of two small test tubes and inactivate it at 56° C. for twenty minutes, together with a little more than

*From the Laboratory of the Beilinson Hospital, Petah Tiqva, Palestine.
Received for publication, August 3, 1942.

1.5 c.c. of saline solution. Remove tubes from water bath and cool to room temperature. Add 0.01 c.c. of the ripened antigen (I) to each of the serum tubes and shake by hand or shaker for three minutes. Add 0.5 c.c. of spinal fluid to one tube and 1.0 c.c. to the other, and again shake for three minutes. The reaction is now read in the usual way. If a precipitate has formed only in the tube containing 1.0 c.c. of spinal fluid, the reaction is weakly positive; if in both tubes, it is considered strongly positive. If only small quantities of spinal fluid are at disposal, the test may be made with one tube and 0.75 c.c. of spinal fluid. To make the reaction more clearly visible, it is advisable to centrifuge at a high speed for about ten minutes. If the reaction is positive, a precipitate on the bottom of the test tube is seen, the supernatant fluid being transparent. After shaking the test tube, the flocculation is distinctly visible. In case of a negative reaction the fluid remains turbid and there is no precipitate. For measuring accurately the small amount of antigen, we use a 0.200 c.c. serologic pipette with a bent tip (Fig. 1), which enables us to direct the fluid to one spot. By using this pipette, dispersion and loss of substance on the wall of the test tube are prevented.

In order to prove that the spinal fluid itself does not affect or modify the reaction, we added to 4 test tubes containing 0.1 c.c. of inactivated Kahn positive serum, the usual quantity of antigen. After shaking the tubes, we added to two, 0.5 c.c. and 1.0 c.c. of negative spinal fluid, and to the other, two equal quantities of salt solution. The reaction in both cases was the same in character and in degree. Negative sera treated with negative spinal fluid never gave positive results.

A serologic reaction for gonococcus and echinococcus antibodies, based on the same principle, will be reported shortly.

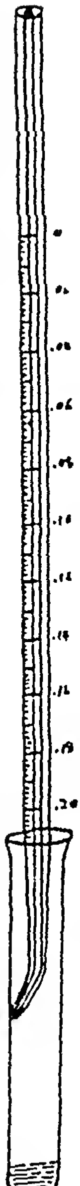

Fig. 1.

AN EFFECTIVE METHOD FOR ANESTHETIZING SMALL ANIMALS*

Harold M. Kaplan, Ph.D., Cambridge, Mass.

IN THE laboratory investigation of clinical problems in which small animals are utilized, the problems of struggling and restraint are present. The difficulties arise particularly in carrying out ether anesthesia without adequate assistance upon animals such as the cat.

One can readily work alone without difficulty by placing not too docile animals within a wooden box. If the dimensions of length, height, and width, respectively, are about 16 × 13 × 11 inches, it adequately accommodates any cat or smaller animal. Windows should be inserted in at least two of the sides so that the animal's condition is observable. A hinged cover is constructed on top of the box.

An ether vaporizer to be used with the box has been devised here. This is illustrated in Fig. 1. It is constructed quickly and easily with little expense, and its parts are obtainable.

The ether is contained in a closed separatory funnel, and is allowed to run through the stopcock into the vaporizing flask when needed. The flask must be Pyrex and widemouthed, a convenient capacity being 500 c.c. It must be fitted with a rubber stopper. Erlenmeyer flasks of this capacity, which take a No. 10 stopper, are manufactured by Corning Glass Works, Corning, N. Y. An eight-ounce widemouthed nursing bottle with a No. 10 stopper may be substituted, but it will not take as much ether. Two wires are each inserted into a glass tube, and the tube at its two ends is flame-sealed around the wire. These shielded wires are inserted through the stopper to extend down into the flask. Near the bottom, each wire leaves the glass shield and is firmly soldered or welded to a broad flat copper electrode; the two electrodes are kept carefully separated to prevent sparking (which might explode the ether). Above the flask, the wires are extended upward by well-insulated cord through a switch to a plug. This may be inserted into any socket carrying alternating current (110 to 220 volts). The switch must be well-enclosed, by tape or other means, to prevent the chance of open sparking.

An aqueous copper sulfate solution is poured inside the flask. Its level must be kept well *above* the electrodes. If the solution is not too concentrated (a pale blue color indicates the proper saturation), its electrical conductivity is small; and thus when the current is applied, its resistance will create heat. This rapidly warms the ether to its boiling point (about 35° C.), and vaporizes it. The vapor is conducted away from the flask in a steady stream through glass and rubber pressure tubing to the animal box. A terminal glass nozzle should penetrate the box through a fitted hole bored at a low level to allow the ether vapors to rise and permeate the whole interior.

*From the Department of Physiology, Middlesex University, Waltham, Mass.
Received for publication, October 19, 1942.

Within the vaporizing flask the volume of ether is always observable, since being light and immiscible with water it rests as a distinct layer above the blue solution. There is no danger of its diffusing downward to the electrode area. Sparking between the electrodes is further minimized by using an alternating current. This alternation also prevents appreciable solution of copper, which would erode the electrodes and make the fluid muddy.

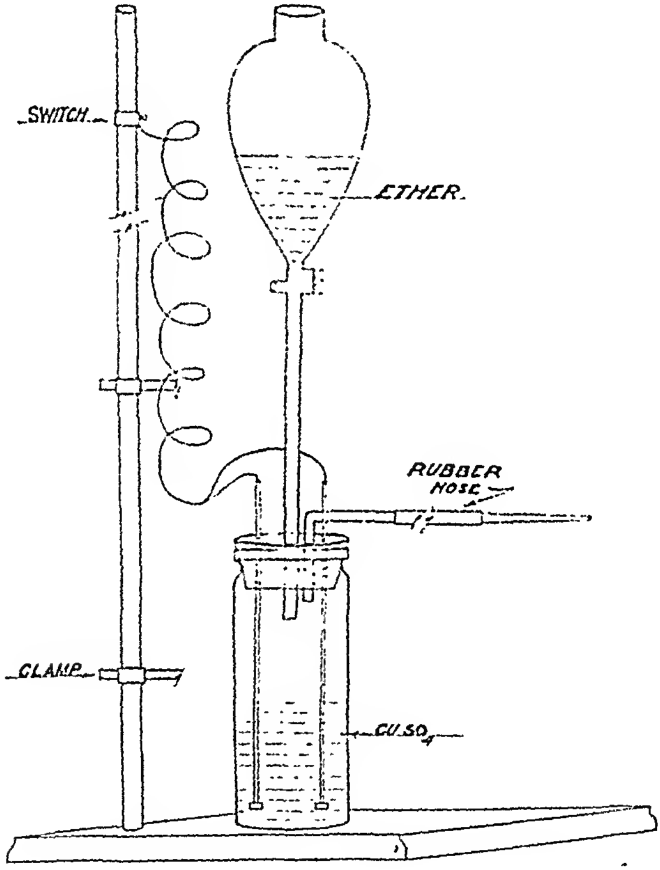

Fig. 1.

We use this apparatus frequently and can state that with ordinary care it is no more dangerous than any other laboratory appliance, although it is unquestionably hazardous in the hands of inexperienced persons. It is quick and sparing of ether. By observation of the ether box, the stages of anesthesia are clearly followed. In the surgical stage the animal may be removed and tied down to an animal board. It is kept anesthetized thereafter by applying a cone to its nose.

CHEMICAL

SERUM BILIRUBIN: A PROCEDURE FOR THE DETERMINATION OF INDIRECT AND DIRECT VALUES

BERNARDO SEPULVEDA, M.D.,* AND ARNOLD E. OSTERBERG, PH.D.†
ROCHESTER, MINN.

THE original van den Bergh technique and the modification to this method introduced by Thannhauser and Andersen have been used extensively for the determination of serum bilirubin. Both procedures, however, present several disadvantages which can be summarized as follows: (1) It is difficult to match the color of azorubin with that of artificial standard solutions; (2) loss of bilirubin occurs in the protein precipitate; (3) values of less than 1 mg. cannot be read accurately; (4) separate determinations of the direct and indirect fractions cannot be made since estimation is on total bilirubin; and (5) in the Thannhauser and Andersen method the personal error involved in the correct differentiation of direct and indirect types of reaction is considerable.

The fact that sera in which the bilirubin gives a direct reaction also contain a varying amount of indirect reacting bilirubin is theoretically of interest. It has been postulated that the proportion between these two types of bilirubins is different in various types of jaundice, and therefore their separate determination should give diagnostic and prognostic information. Consequently, several techniques have been devised to measure separately the quantity of direct and indirect fractions of total bilirubin; furthermore, new techniques have been devised which avoid the deficiencies of the former methods and provide for the accurate determination of bilirubin. In this paper a technique for determination of bilirubin is described which is based in part on two methods previously outlined.

EARLIER METHODS FOR MEASURING BILIRUBIN

Varela Fuentes[1,2] developed a technique on the basis of the solubility of indirect reacting bilirubin in chloroform. In his procedure the indirect reacting bilirubin. Therefore we subtract from the final reading of direct bilirubin this After evaporation of the chloroform the dry residue is redissolved in chloroform and alcohol and then diazotized. The concentration of direct bilirubin in the same sample of serum is determined by adding diazo reagent and alcohol after extraction of the indirect bilirubin with chloroform. The precipitate is separated by filtration, and the reading is made on the filtrate by means of a standard colorimeter.

The technique for the extraction of indirect reacting bilirubin proposed by Varela Fuentes appeared to us to be the most efficient method thus far reported.

*Fellowship in Medicine, Mayo Foundation.
†From the Section on Clinical Biochemistry, Mayo Clinic, Rochester, Minnesota.
We wish to express our appreciation to Miss Elizabeth Machy for technical assistance.
Received for publication, March 5, 1943.

It has been used in the work to be described in this paper with slight modifications which were made to adapt it to the photelometer.

Several objections can be raised to the use of the method of Varela Fuentes for the determination of direct bilirubin; essentially it has the same disadvantages as the original van den Bergh method and the Thannhauser and Andersen technique, that is, loss of bilirubin in the protein precipitate and the difficulties of matching color with that of artificial standard solution.

One of us (A. E. O.)[3] modified the technique for determination of bilirubin proposed by van den Bergh and Grotepass[4] in order to adapt it for reading in the photelometer. Their procedure for determination of direct reacting bilirubin is based on the fact, known since the first publications of van den Bergh, that this fraction couples immediately with the *diazo* reagent in the serum; the addition of 96 per cent alcohol is unnecessary for the reaction. In their technique 50 per cent buffer alcohol (final concentration in tube, 25 per cent) is used to maintain a constant pH in the tubes for the direct and indirect reaction. The use of alcohol, however, even in such a low concentration, is a cause of error, for it allows part of the indirect bilirubin to react and thus increases the color of the direct reaction. This fact has been mentioned previously by Malloy and Evelyn[5] and has been confirmed in the present investigation. The buffer alcohol is not necessary when the photelometer is used, since the differences in pH do not exert any influence on the reading. In the determination of indirect bilirubin the method obviously can be applied only in those cases in which the serum contains this fraction alone, as in certain cases of hemolytic icterus. When both fractions are present, as usually occurs in obstructive and parenchymatous jaundice, the method really determines total bilirubin. Even so, the estimation is incomplete, since as mentioned before some direct bilirubin is carried out in the protein precipitate.

Malloy and Evelyn developed a procedure to make separate determinations of direct and total bilirubin. A considerable improvement is made by the use of 50 per cent alcohol in the measurement of total bilirubin; Malloy and Evelyn have demonstrated that complete coupling of the bilirubin takes place in the presence of 50 per cent alcohol without any precipitation of protein. The estimation of direct bilirubin is based on the same principle we have used, namely, the ability of this fraction to react in water solution; the reading is also made in a photelometer. Later some differences between the two methods will be mentioned.

DESCRIPTION OF PRESENT TECHNIQUE

Qualitative Test.—The qualitative test is first performed on a sample of serum as follows. To 1 c.c. of serum, generally diluted, 2 c.c. of diazo reagent is added. Three well-known results may be obtained:

1. A direct reaction may occur. The color change then is detected as soon as serum and diazo reagent are mixed together; it reaches its maximal intensity in from sixty to ninety seconds. The color is pink in undiluted serum and purplish in diluted serum.

2. An indirect (delayed or negative direct) reaction may occur. No change of color then is noted during the first two minutes after addition of the diazo

reagent. Between four and ten minutes after the diazo reagent is added a golden color appears, in about thirty minutes a brownish color, and after one to one and a half hours the characteristic pink color develops. This color is similar to that of the direct reaction in the undiluted serum.

3. A biphasic, direct reaction may occur. This type of reaction has been found only three times in more than 400 cases observed by us. The color which appears during the first minute is not a typical pink, but a brownish red which generally reaches its maximal intensity in two or three minutes after the diazo reagent is added.

Quantitative Test.—After the qualitative test, quantitative determination of direct and indirect reacting bilirubins is made.

Direct Reacting Bilirubin.—The quantitative determination of direct reacting bilirubin is carried out only if either a direct or biphasic reaction has occurred in the qualitative test. The volume of the serum and diazo reagent is made up to 10 c.c. with distilled water, and the photelometer reading is made during the first ten minutes after the water is added.

In spite of the fact that a filter having a maximal transmission at 530 to 535 millimicrons is used, the color of the serum itself influences the reading. By making a control series of readings with normal sera against water "blank," we have found an average photelometer reading of 96 which equals 0.4 mg. of bilirubin. Therefore we subtract from the final reading of direct bilirubin this correction factor of 0.4 mg. This procedure is accurate and avoids the preparation of a normal "serum blank" for every determination.

Indirect Reacting Bilirubin.—To another 1 c.c. portion of the serum in a centrifuge tube marked at 10 c.c. is added 2 c.c. of sodium sulfate (12 per cent solution prepared from anhydride), and the solution is mixed. To this is added 5 c.c. (or more) of chloroform. The tube is shaken vigorously for thirty seconds, then centrifuged for about five minutes at high speed. The yellow chloroform extract remains under the turbid serum. The capillary end of a pipet is introduced to the bottom of the tube and almost all the chloroform is aspirated. A slanting mirror should be placed under the tube so the operation may be watched. The aspirated chloroform is transferred to a test tube of at least 2 cm. in diameter. Extraction of the serum is repeated with a new portion of chloroform and the second extract is added to the first. Extraction must be repeated until the chloroform is colorless. Usually three to four extractions are sufficient.

The combined chloroform extracts in the test tube are evaporated in a water bath at 80° C. The dry adherent residue is taken up in 0.5 c.c. of chloroform and 2 c.c. of 96 per cent alcohol, which dissolve the bilirubin. To this is added 0.5 c.c. of a fresh diazo reagent (final volume 3 c.c.). The red color of azobilirubin does not develop completely until after ten minutes. The reading is made in the photelometer against water blank.

We have used the Cenco Sheard-Sanford photelometer equipped with a Cenco No. 2 filter which has a transmission range of 550 to 700 millimicrons. The calibration curve is obtained by the following procedure: Five milligrams of purified bilirubin is dissolved in 100 c.c. of chloroform, and 10 c.c. of this solution is evaporated under carbon dioxide on a water bath, until it is nearly dry. To the residue is added 80 c.c. of a solution consisting of 50 per cent alcohol which contains 10 c.c. of a buffer solution of pH 6.6 to every 100 c.c. The buffer alcohol solution is heated for some time in order to evaporate the chloro-

form. Next, the solution is brought to room temperature and to it is added 20 c.c. of the reagent consisting of Solution A, 1 Gm. sulfanilic acid, 15 c.c. of 25 per cent hydrochloric acid with distilled water up to 1 liter, and Solution B, 0.5 per cent sodium nitrite in aqueous solution. Ten cubic centimeters of Solution A is mixed with 0.3 c.c. of Solution B shortly before use. Additional buffer containing alcohol is added to the solution after the reagent and the total quantity has been brought up to 100 c.c. The pigmented solution which is to be examined must be left in the dark for fifteen minutes in order to complete the coupling.

The concentration of bilirubin as its azo derivative equals *1/200,000* or *0.5* mg. in 100 c.c. This corresponds to a concentration of bilirubin of 5 mg. in each 100 c.c. of serum when the analysis is carried out on 1 c.c. of serum and the final volume equals 10 c.c.

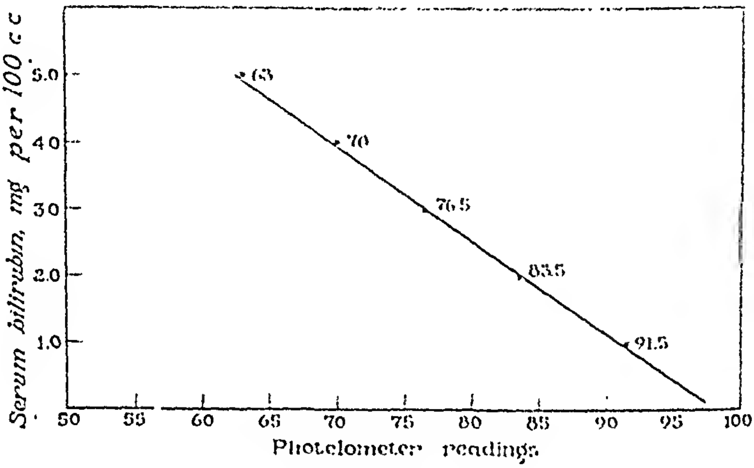

Fig. 1.—Curve of photelometer readings showing relationship with concentration of serum bilirubin.

Other points on the curve are obtained in a similar manner using volumes of the original solution of bilirubin of 8 c.c., 6 c.c., 4 c.c., and 2 c.c. By this procedure, as is shown in Fig. 1, there is obtained, for practical purposes, a straight line relationship* up to values corresponding to a concentration of 3 mg. of bilirubin in each 100 c.c. of serum. If higher concentrations than this value are obtained, it is necessary to dilute the serum previous to the determination in order to obtain a value of less than 3 mg. in each 100 c.c. Appropriate factors are then applied to obtain the final value of bilirubin. This procedure is adopted because of the fact that when values of more than 3 *mg. per* 100 c.c. are subjected to the diazo reaction, the photelometric readings depart too greatly from the assumed straight line relationship. Also, the concentration of the compound produces a dark color and turbidity may develop.

COMMENT

Direct Reacting Bilirubin.—We have found that in serum diluted before the addition of diazo reagent the reading of direct bilirubin yields higher figures

*It is known that, in the case of solutions of substances which possess characteristic absorption zones, the concentration (C) is proportional to the negative logarithm of the transmitted light (I); that is, $C = -k \log I$. For the range of dilutions used in these investigations, however, departures from the linear relationship as shown in Fig. 1 and the values obtained from the semilogarithmic plot are not considered as being significant.

than in undiluted serum. Serum diluted after coupling behaves like undiluted serum. The higher the concentration of pigment, the greater the difference in the results. A curve of the quantities obtained at different dilutions can be drawn demonstrating that relationship, until a limit of dilution is reached, after which no further variation occurs (Table I).

These differences were first attributed to variations in the color of the reaction, owing to changes in pH, the azorubin in undiluted serum being red-pink and purplish or red-violet in diluted serum. In the first case the proteins and other buffer mechanisms present in serum neutralize partially the acid diazo reagent giving a final reaction that is weakly acid. In the diluted serum this does not occur and a lower pH results. Griffiths and Kaye[6] have mentioned the diverse tones of color present according to the variations in pH. In the experiment described in Table I, however, we found that these differences in color did not exert an influence on the reading; also that the final results were comparable when several different fluids were used to make the dilutions.

TABLE I

READINGS ON SERUM DILUTED BEFORE AND AFTER COUPLING

	BILIRUBIN, MG. PER 100 C.C. AFTER USE OF DILUTIONS OF		
	1:10	1:20	1:40*
A. Serum diluted after coupling	22.6	24.0	24.0
B. Serum diluted before coupling			
Dilution with serum of normal dog†	26.6	32.6	37.6
Dilution with diazo reagent	24.6	27.6	31.6
Dilution with water	27.6	31.6	35.6

*Dilutions greater than 1:40 gave same results.
†The serum of a normal dog contained 0.05 mg. per 100 c.c. of indirect bilirubin.

The higher readings obtained in serum diluted before coupling may be explained as follows: When the concentration of direct bilirubin is high, the diazo reagent is unable to cause all the bilirubin to react; consequently a variable amount remains undetermined. In diluted serum less pigment is present, and with the same quantity of diazo reagent the combination is complete and the total quantity of direct bilirubin present is determined. The proper dilution for serum in a case of jaundice can be judged with relative certainty by the intensity of the yellow color of the serum. We usually make a 1:5 or 1:10 dilution. After diazotization has taken place, the reading is made in the photelometer; if the reading is below the equivalent of 3 mg. (above 75 on the scale), the dilution is correct and the calculation can be made therefrom in milligrams of bilirubin. When the reading is higher than 3 mg. (below 75 on the scale), the dilution is increased. With diluted serum we have found that the most accurate results are obtained if the readings are kept between 1 and 3 mg. (75 to 90 on the scale). The disadvantage of repetition of the reading is necessary only in case of unknown sera and with practice it can usually be avoided.

We do the reading of direct bilirubin the first ten minutes after the water is added, because after this time the indirect bilirubin also takes part in the reaction. It is well known that the indirect bilirubin can react slowly in water solution, and this is evidenced by the fact that in sera in cases of hemolytic jaundice the development of color starts usually after ten minutes. When both

fractions are present, we have observed differences of several milligrams between the readings at five and thirty minutes. This is especially true when the amount of indirect bilirubin is high.

Indirect Reacting Bilirubin.—Grunenberg[7] first noted the different behavior with chloroform of direct and indirect reacting bilirubins and demonstrated that the pigment in serum from a patient who had hemolytic jaundice was soluble in chloroform while that from a patient who had obstructive jaundice was not. Andrewes,[8] Collinson and Fowweather,[9] Roberts[10] and Newman[11] have confirmed these results. Hunter[12] included the different solubilities in chloroform in a summary of the properties of direct and indirect reacting bilirubins.

De Castro[13] presented a method for the determination of both types of bilirubin in which the indirect type of bilirubin was extracted from the serum with chloroform. Varela Fuentes showed that with this technique, when 2 c.c. of chloroform were used and the extraction was done only once, 50 per cent of the indirect reacting bilirubin remained in the serum. Consequently he modified the method so that 5 c.c. of chloroform were used and several extractions were made. In most cases extraction by this method was complete, but when the concentration of bilirubin was high, a small portion of the pigment remained in the serum. With the use of the 12 per cent solution of sodium sulfate, extraction was improved and the chloroform removed practically all the indirect bilirubin.

Before adopting the technique of Varela Fuentes it was necessary for us to confirm that: (1) chloroform extracts only indirect reacting bilirubin without affecting the direct type, and (2) chloroform extracts the indirect reacting bilirubin completely. This was done as follows:

In serum in which both direct and indirect reacting bilirubins were present, the direct bilirubin was measured by the method recommended in this paper. In a different sample of the same serum complete extraction of the indirect bilirubin with chloroform was carried out. After extraction, a mixture of serum, sodium sulfate, and chloroform residues remained in the tube. After centrifuging, the three layers separated: the upper layer was a yellow liquid (mostly sodium sulfate in which was dissolved part of the direct bilirubin); the middle layer was the protein precipitate which carried the remainder of the direct reacting bilirubin, and the bottom layer consisted of a small quantity of colorless chloroform. The upper layer was poured into another tube and the chloroform was evaporated in the presence of carbon dioxide to prevent oxidation of the bilirubin. The dry precipitate was dissolved in 10 to 20 c.c. of 5 per cent urea solution. Usually all the precipitate went into solution but sometimes a portion remained insoluble. To this solution was added the yellow upper layer mentioned and 1 c.c. of the mixture was diazotized. A direct reaction was obtained and the reading was made in the photelometer. In a good proportion of cases approximate agreement was found between the values for direct bilirubin and those of bilirubin recovered from serum after extraction with chloroform (Table II). Cases in which recovery of direct bilirubin was not complete were those in which a portion of the precipitate containing some bilirubin was insoluble. Apparently this fact accounts for the incomplete recovery of direct reacting bilirubin in these cases.

It is easy to observe that after several extractions the original yellow serum of hemolytic jaundice turns a whitish color. On the other hand, the serum of ob-

structive jaundice remains yellow no matter how many extractions are made with chloroform. A more definite proof of the complete extraction of bilirubin with chloroform was obtained by the following method: Three c.c. of 96 per cent alcohol were added to serum from a patient who had hemolytic jaundice after complete extraction with chloroform. The mixture was shaken and centrifuged. The supernatant fluid was pipetted off and diazotized. In a great majority of cases no color developed; its absence indicated the absence of bilirubin in the serum. We found that the only time at which a small portion was not extracted was in the presence of hemolytic jaundice, when the concentration of bilirubin in the serum was high. This portion was never more than 15 per cent of the whole amount of indirect reacting bilirubin present. Therefore, from a practical standpoint, it may be considered that chloroform produces a complete extraction of indirect reacting bilirubin. In this point we agree with the results reported by Varela Fuentes.

TABLE II

VALUES FOR DIRECT REACTING BILIRUBIN IN SERUM BEFORE AND AFTER EXTRACTION OF INDIRECT BILIRUBIN WITH CHLOROFORM

DIRECT BILIRUBIN		INDIRECT BILIRUBIN
BEFORE EXTRACTION	AFTER EXTRACTION	
13.8	14.4	3.9
14.1	13.2	2.5
44.6	43.7	3.7
27.5	28.0	2.7
16.8	17.0	2.7
22.6	23.0	2.4

TABLE III

COMPARISON BETWEEN NEW METHOD AND THE THANNHAUSER AND ANDERSEN METHOD IN HEMOLYTIC PROCESSES

DIAGNOSIS	NEW METHOD		THANNHAUSER AND ANDERSEN METHOD	
	DIRECT BILIRUBIN	INDIRECT BILIRUBIN, MG. PER 100 C.C.	REACTION	MG. PER 100 C.C.
Congenital hemolytic icterus	0	3.2	Indirect	2.6
Congenital hemolytic icterus	0	10.0	Direct	9.5
Congenital hemolytic icterus	0	2.5	Indirect	2.9
Congenital hemolytic icterus	0	1.3	Indirect	1.6
Acquired hemolytic icterus	0	2.8	Direct	4.1
Subacute hemolytic anemia	0	1.5	Direct	2.4
Acquired hemolytic anemia	0	5.4	Direct	5.8
Acute hemolytic icterus	0	9.6	Direct	10.7

COMPARISON OF NEW METHOD WITH OTHER METHODS

Thannhauser and Andersen Procedure.—Qualitative reaction.—The qualitative results obtained with the new technique and with the Thannhauser and Andersen technique in a group of cases of hemolytic processes are listed in Table III. In five cases the results with the Thannhauser and Andersen technique were incorrect. Apparently the short period of time, two minutes, between the addition of the diazo reagent and the reading of the qualitative test used in the Thannhauser and Andersen method accounts for the wrong reports. When the concentration of indirect bilirubin is high, a change of color starts at the

end of two minutes; this color is never the characteristic pink or red violet of direct bilirubin but may lead to misinterpretation.

Quantitative Reaction.—The quantitative results from the same two techniques are shown in Fig. 2. In every case the values of total bilirubin were higher with the new technique. The higher the quantity of bilirubin present the greater was the difference in the readings given by the two methods. Occasionally the concentration was found to be as much as three times as high with the new technique.

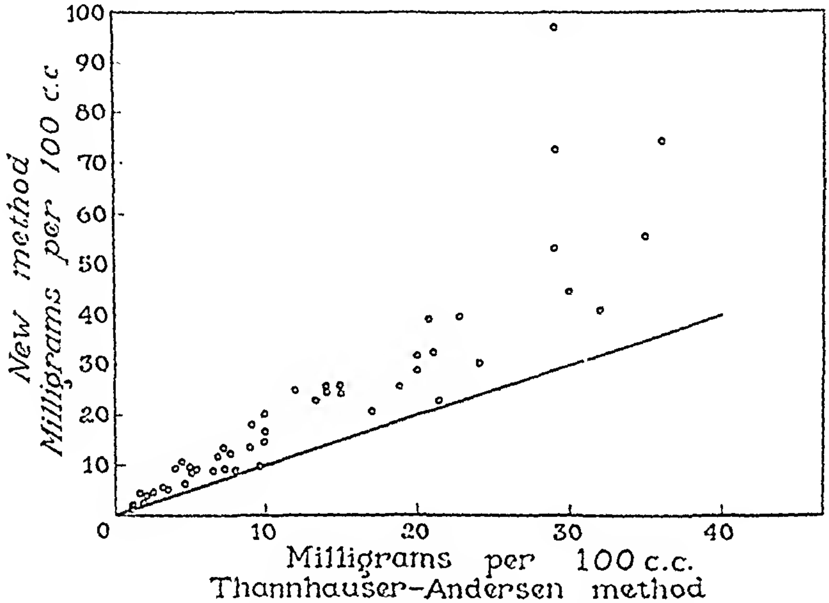

Fig. 2.—Determination of bilirubin in 65 cases of intrahepatic and obstructive jaundice. Quantitative results.

TABLE IV

COMPARISON OF MALLOY AND EVELYN TECHNIQUE AND THE NEW TECHNIQUE: QUANTITATIVE AND QUALITATIVE RESULTS

CASE	BILIRUBIN, MG. PER 100 C.C.				
	MALLOY-EVELYN TECHNIQUE		NEW TECHNIQUE		TOTAL
	DIRECT	TOTAL	DIRECT	INDIRECT	
1	1.0	2.5	Negative	2.5	—
2	0.3	0.8	Negative	0.3	—
3	0.7	1.2	Negative	0.8	—
4	1.2	1.5	1.5	0.3	1.8
5	5.0	7.4	6.5	0.2	6.7
6	10.0	13.5	13.6	1.1	14.7
7	7.5	10.4	10.6	1.0	11.6
8	0.7	1.7	2.6	0.6	3.2

Malloy and Evelyn Technique.—In Table IV the results of the new technique and the Malloy-Evelyn technique are compared. In the latter, determinations are made of the direct reacting bilirubin and of total bilirubin. Quantitative results for total bilirubin were similar, and from a practical standpoint both methods apparently are equally reliable. The qualitative results disagreed, however, because in several cases "direct" reacting bilirubin was found with

the Malloy-Evelyn technique whereas it was not found with the new technique. The explanation for this apparent contradiction is as follows: In the Malloy and Evelyn technique readings for direct bilirubin are always made regardless of the qualitative type of reaction. In the new technique, readings for direct bilirubin are made only when the qualitative reaction gives evidence of the presence of direct bilirubin. As has been stated, indirect bilirubin can react slowly in water solution; consequently, if a reading is made thirty minutes after the diazo reagent has been added to a serum from a normal person or to one from a patient who has hemolytic jaundice, the coupling is advanced enough to give a false direct reaction. This ability of the indirect bilirubin to react slowly in water solution explains, in our opinion, the results reported by Cantarow, Wirts, and Hollander,[14] who used the Malloy and Evelyn technique. These writers made the reading at the end of thirty minutes and found what they considered direct reacting bilirubin in the serum of normal persons, in cases of hemolytic jaundice, and in cases of hepatic and biliary disturbances; the values for total bilirubin, however, were within normal limits. Furthermore, they found that in some cases of hepatic and biliary disease the qualitative test gave a negative direct result while the quantitative procedure indicated the presence of "direct" bilirubin. This apparent contradiction is due to the fact that in the period of time which elapsed before the reading was made some of the indirect bilirubin was changed to azorubin. It is true that those results can be taken as a conventional term and probably the values would be comparable in the same group of disorders. We think it preferable, however, to establish a clear distinction between the qualitative reactions and evaluate the direct bilirubin only when its presence has been proved by an immediate reaction.

SUMMARY

A technique for the determination of direct and indirect reacting bilirubin present in serum is described. This procedure is a combination of two previously described methods which have been somewhat modified. A comparison has been made between values obtained with the modified procedure and those obtained with such standard methods as the Thannhauser-Andersen modification of the van den Bergh method and the Evelyn and Malloy procedure. Evidence is presented which demonstrates the difference in solubility of the direct and indirect reacting types of bilirubin and it is shown that this difference allows their separate determination. The ratios in which the two types occur are also given. The clinical importance of these two types of bilirubin is to be presented in another paper.

STUDIES OF PANCREATIC FUNCTION*

I. The Determination of the Lipolytic Enzymes of Blood Serum

Norman P. Goldstein, M.A., and Joseph H. Roe, Ph.D.
Washington, D. C.

THE DIAGNOSIS of pancreatic disease, other than diabetes mellitus, is difficult, a situation due in part to the limitations of laboratory methods. The laboratory approach to this problem has been along two general pathways: (1) the determination of enzymes of pancreatic origin (amylase, lipase) in the blood serum; (2) the estimation of the amount, bicarbonate content, and enzymes of the external secretion of the pancreas following pancreatic stimulation.

In acute inflammatory lesions of the pancreas, where either a disintegration of pancreatic tissue or obstruction in the ducts causes the back-passage of abnormal quantities of pancreatic enzymes into the blood stream, the determination of the amylase or lipase content of the blood serum has been found very useful. In those lesions of the pancreas where there is a decrease in the amount of enzymes secreted, however, the information obtainable from blood studies is without significance. The indications of an elevation of pancreatic enzymes in the blood serum, in the presence of the other clinical findings, are clear, but the observation in the serum of a lower than normal content of enzymes, which have characteristics similar to those secreted by the pancreas, is difficult to interpret because these enzymes have an extrapancreatic, as well as pancreatic, origin.

---

*From the Department of Biochemistry, School of Medicine, The George Washington University.
Received for publication, May 14, 1943.

In those pancreatic diseases which are characterized by a deficient external secretion, the clinician obtains some information by observations of the stools. Bulky stools, containing undigested muscle fibers, starch, and increased fat, suggest a deficiency in pancreatic secretion. Pratt[1] has stressed the importance of a gross inspection of the stools, and he calls attention to the rather specific relation of creatorrhea to pancreatic insufficiency.

Lagerlöff[2] states that the determination of the enzyme content of the stools is worthless. According to this author, lipase is inactivated in the feces. Moreover, amylase originates in the saliva as well as in the pancreatic juice.

Recently, important advances have been made in the development of laboratory procedures for the direct testing of pancreatic function. Ågren and Lagerlöff[3] appear to be the first investigators to have developed a successful technique for collecting pancreatic juice uncontaminated with saliva or gastric juice. In 1936 these authors described a procedure in which a double lumen tube is introduced into the upper alimentary canal and the contents of the stomach and duodenum are removed simultaneously by suction, before and after the intravenous administration of secretin. Ågren and Lagerlöff, also Diamond and Siegel[4] in this country, have reported that the secretin test gives much valuable information concerning disturbed function of the pancreas, particularly in chronic states.

A new method for evaluating pancreatic function has recently been reported by Free, Beams, and Myers.[5] In this procedure a Rehfuss or Einhorn duodenal tube is introduced into the stomach and the gastric contents are removed. The tube is then passed into the duodenum and a twenty-minute fasting sample of duodenal contents is collected. Twenty-five c.c. of olive oil are then injected slowly through the tube, and after ten minutes siphonage is started again. Three twenty-minute samples of duodenal juice are collected. All samples of duodenal juice are examined for total volume, proteinase, amylase, lipase, and icteric index. Data were obtained upon patients with pancreatic disease which showed marked departures from normal values. These authors report results as good by the use of a single duodenal tube as with a double lumen tube. Exclusion of gastric juice results from the inhibitory effect of olive oil on gastric secretion and motility. This test appears to be on a sound basis and has much in its favor in the way of simplicity and practicality of procedure.

Numerous methods for the determination of lipidolytic enzymes have been proposed. These have involved the use of titration, stalagmometric, manometric, and electrometric techniques. Of these, representative ones will be discussed here. In early reports in the literature, the fatty acid liberated by the hydrolysis of substrate was titrated with standard alkali. In 1911 Rona and Michaelis[6] developed a stalagmometric method, using tributyrin as a substrate. In this method the increase in the number of drops of a solution containing enzyme, substrate, and buffer, due to changes in surface tension, is taken as a measure of enzyme activity. Rona and Lasnitzki,[7] in 1924, devised a manometric method for the estimation of lipase. This method measures manometrically the volume of carbon dioxide released from sodium bicarbonate by the action of butyric acid, the amount of butyric acid being dependent upon the concentration of the

lipase, which promoted the hydrolysis of tributyrin. This method has certain advantages: the pH of the solution is readily maintained and one of the end products of the reaction is continuously removed. A titration method for the determination of lipase was published by Willstätter, Waldschmidt-Leitz, and Memmen[8] in 1923. In this procedure the fatty acid liberated by action of the lipase upon a buffered olive oil emulsion is titrated with standard alkali. In 1932 Cherry and Crandall[9] published a modification of the Loevenhart[10] (1907) method for the determination of esterase, in which the fatty acids resulting from the hydrolysis of a buffered ester or fat emulsion by the enzymes of a biologic material are titrated with twentieth-normal sodium hydroxide. These investigators reported that after ligation of the pancreatic ducts in dogs, they could demonstrate the presence in serum of an olive oil-splitting enzyme (lipase) which normally did not occur in the blood serum. They also found that the activity of an enzyme normally present in blood, as measured by the hydrolysis of ethyl butyrate or tributyrin (esterase), did not show uniform increases following pancreatic duct ligation. They, therefore, concluded that their test for lipase was specific for pancreatic injury. Recently, Troescher and Norris[11] have proposed a method in which the action of the enzyme upon ethyl butyrate in a phosphate buffer solution is measured by the change in pH of the solution due to the butyric acid liberated.

Our interest in this problem arose from a realization of the limitations of present methods for determining the lipidolytic enzymes of the blood. The serum lipase determination has been reported to be especially useful in the diagnosis of pancreatic lesions of the obstructive type.[12-14] The methods used in this work require a 24-hour incubation of serum with substrate. Obviously a procedure for estimating the concentration of an enzyme which requires twenty-four hours of hydrolysis is undesirable from both a theoretical and practical point of view. It is well known that to make an accurate determination of the concentration of an enzyme, one should measure the initial rate of hydrolysis. Furthermore, when a serum lipase determination is desired, the patient usually is acutely ill and waiting for twenty-four hours on an analysis is very objectionable.

Of the various methods proposed for estimating lipase or esterase action, we believe the most suitable procedure for clinical work is the simple titration of the fatty acid liberated by enzymic activity upon a suitable substrate. In attempting to develop a method which would be more accurate and sensitive our attention was directed to a consideration of the following conditions: (1) the substrate used; (2) the emulsifying agent; (3) the pH at which the test is run and therefore the buffers used; (4) removal of the end products of the reaction; (5) the temperature at which the test is carried out; (6) the method of stopping the enzymatic hydrolysis. Our results and conclusions with respect to each of these conditions are set forth below.

SELECTION OF SUBSTRATE

Cherry and Crandall[9] studied the activity of pancreatic and liver extracts and blood serum upon 21 different esters, with particular emphasis upon ethyl butyrate, tributyrin, and olive oil. These investigators abandoned the use of

ethyl butyrate and tributyrin on the grounds that the latter substances were split by blood esterase, whereas only blood lipase splits olive oil. Other investigators, however, have used ethyl butyrate and tributyrin on the same basis as olive oil. Two other new and possible substrates, benzyl butyrate and benzyl stearate, were suggested by the work of Balls and Matlack,[15] who found that the esters of benzyl alcohol are split more rapidly than those of other alcohols. Benzyl stearate was eliminated from use because at ordinary temperatures it is a solid and is extremely difficult to emulsify. The five substrates selected for study were ethyl butyrate, benzyl butyrate, tributyrin, olive oil, and triolein. All five of these exist in the liquid form at room temperatures and are fairly easy to emulsify; two are simple esters and three are glycerides, a selection which appeared to offer an opportunity to study the question of whether the biologic fluid being examined contains an esterase, a lipase, or both. Triolein was selected in order to have a pure triglyceride of a known long chain fatty acid for comparison with olive oil, an impure mixture of glycerides and other substances.

TABLE I

RATE OF SPLITTING OF DIFFERENT SUBSTRATES

SUBSTRATE	GLYCEROL EXTRACT OF PANCREAS	GLYCEROL EXTRACT OF LIVER	HUMAN SERUM	CAT SERUM	RABBIT SERUM	DOG SERUM
Ethyl Butyrate (0.25 c.c.)	5.20 (1 hr.)	4.67 (1 hr.)	0.33 (24 hr.)	0.41 (24 hr.)	0.28 (24 hr.)	1.90 (24 hr.)
Tributyrin (0.25 c.c.)	13.40 (1 hr.)	2.68 (1 hr.)	0.83 (1 hr.)	1.01 (1 hr.)	1.19 (3 hr.)	1.95 (1 hr.)
Benzyl Butyrate (0.25 c.c.)	9.77 (1 hr.)	6.52 (1 hr.)	0.49 (3 hr.)	0.65 (3 hr.)	0.53 (3 hr.)	2.19 (3 hr.)
Olive Oil (1.00 c.c.)	6.24 (1 hr.)	00 (24 hr.)	0.18 (24 hr.)	0.26 (24 hr.)	0.22 (24 hr.)	0.38 (24 hr.)
Triolein (0.25 c.c.)			0.15 (24 hr.)	0.31 (24 hr.)		0.33 (24 hr.)

Expressed as c.c. of 0.1 N alcoholic KOH per c.c. of serum or c.c. of tissue-glycerol preparation. Parentheses show amount of substrate in column 1 and time of hydrolysis elsewhere.

The results of this study are recorded in Table I. Our data show that the greatest amount of hydrolysis is obtained with tributyrin as a substrate in experiments with glycerol extract of pancreas and with human, cat, and rabbit serum; whereas with glycerol extract of liver, benzyl butyrate gave a higher value. These results suggest that tributyrin should be the substrate of choice to obtain the most sensitive test when analyzing for enzymes of pancreatic origin and that benzyl butyrate would be the most sensitive substrate for enzymes of liver origin.

THE EMULSIFYING AGENT

For emulsifying agents a number of substances have been used for measurement of lipidase action. Cherry and Crandall[6] favored acacia; Willstätter, Waldschmidt-Leitz, and Memmen[4] used albumin; and Balls, Matlack, and Tucker[16] have utilized a glycerol solution of ox bile. We carried out a series of estimations to determine the most effective emulsifying agent. The data of

Table II show that the bile-glycerol mixture, prepared according to Balls, Matlack, and Tucker,[16] is the most favorable emulsifying agent when benzyl butyrate is used as substrate; in view of these results it was decided to use bile as the emulsifying agent in our experiments.

THE pH AND SELECTION OF BUFFERS

Balls, Matlack, and Tucker[16] observed that pancreatic lipase does not appear to have a very sharp pH optimum. Experiments with tristearin as substrate and NH_3—NH_4Cl mixture as buffer at pH 8.2 to 8.4 and 7.2 to 7.5 showed very little difference in the rates of hydrolysis. Willstätter and Waldschmidt-Leitz[17] found the optimum pH values for pancreatic lipase were 9.2 and 8.3 with olive oil and tributyrin, respectively, as the substrates. With tripropionin as substrate, Weinstein and Wynne[18] found the optimum pH is 7.2 with phosphate-borate buffer and 9.3 with a glycine buffer. Anrep, Lush, and Palmer,[19] using a phosphate buffer and glycerol triacetate as substrate, began their hydrolysis at a pH of 7.8 and permitted a shift in pH to 7.0. They considered a pH below 7.0 to be too low for satisfactory quantitative studies with lipase.

TABLE II

EMULSIFYING POWER OF DIFFERENT EMULSIFYING AGENTS

SUBSTRATE	BILE (DIFCO)	NA. TAURO-CHOLATE (MERCK)	NA. TAURO-CHOLATE (PFANSTIEHL)	NA. GLYCO-CHOLATE (PFANSTIEHL)	FRESH EGG ALBUMIN SOLUTION	DRIED EGG ALBUMIN SOLUTION	5 PER CENT DUPONOL SOLUTION	5 PER CENT ACACIA SOLUTION
Benzyl Butyrate (0.240 Gm.)	11.01	5.75	8.56	5.60	1.99	2.55	0.43	3.21

Expressed as c.c. of 0.1 N alcoholic KOH using 5 c.c. of the emulsifying agent and 1 c.c. of glycerol preparation of calf pancreas. Time of hydrolysis was one hour.

From the work discussed above, it appears that one should carry out the hydrolysis at a pH somewhere within the range of 7.0 to 9.2. In view of the observations mentioned, we decided to fix the buffering conditions so that the initial pH is 8.2 to 8.4, and the pH at the conclusion of the hydrolysis is above 7.0. Under the conditions of our procedure, some shifting in pH is permitted, but this is desirable to avoid using excess quantities of buffer which would have an inhibiting effect. The buffer we found most suitable for our work was sodium diethyl barbiturate, and the amount we determined to be most effective was 0.05 Gm. in the final volume of the test used which is 26 c.c.

In the hydrolysis mixture set up for our method 3 c.c. of 0.1 N butyric or oleic acid are required to shift the pH from 8.4 to 7.0. The buffering system in this procedure, therefore, has the capacity to permit optimum buffering with blood sera having concentrations of lipidolytic enzymes up to 300 units per 100 c.c. If concentrations greater than the latter are encountered, the determination may be repeated, using less serum, to obtain greater accuracy.

In Table III are presented data which show the effectiveness of the buffering system we use in holding the pH within a satisfactory range. This is an important feature of our method; the pH at the end of the hydrolysis is still

in the favorable range, unless very high concentrations of enzymes are encountered, in which case a smaller sample of serum is analyzed. In the Cherry and Crandall method, which has received widespread clinical use in this country, a phosphate buffer mixture with a pH of 7.0 is employed. This is at the lower margin of the pH range recommended by other authors for pancreatic lipase; furthermore, the fatty acid liberated during the hydrolysis shifts the pH to a still lower value, resulting in a corresponding decrease in the sensitivity of this test.

TABLE III

CHANGES OF PH DURING HYDROLYSIS

SUBSTRATE	SERUM	TIME OF HYDROLYSIS	CONTROL PH	PH AFTER HYDROLYSIS
Ethyl Butyrate (0.25 c.c.)	Cat	24 hr.	8.20	7.64
Ethyl Butyrate (0.25 c.c.)	Human	24 hr.	8.20	7.95
Tributyrin (0.25 c.c.)	Cat	3 hr.	8.16	6.20
Tributyrin (0.25 c.c.)	Human	1 hr.	8.31	7.90
Benzyl Butyrate (0.25 c.c.)	Cat	3 hr.	8.15	7.55
Benzyl Butyrate (0.25 c.c.)	Human	3 hr.	8.30	8.06
Olive Oil (1.00 c.c.)	Cat	24 hr.	8.15	7.63
Olive Oil (1.00 c.c.)	Human	24 hr.	8.22	8.09

Using 50 mg. of sodium diethylbarbiturate for each substrate in a hydrolysis with 1 c.c. of serum. Measurements made with a glass electrode.

REMOVAL OF THE END PRODUCT OF HYDROLYSIS

Willstätter, Waldschmidt-Leitz, and Memmen,[8] in 1923, instituted the use of calcium chloride to aid the hydrolysis of a fat by lipase. They attributed their favorable results to the formation of an adsorption compound, fat-calcium-albumin-lipase. Balls, Matlack, and Tucker[16] have continued the use of calcium chloride to aid the reaction. These investigators offer the much more reasonable explanation that the calcium ion combines with the fatty acid liberated in the hydrolysis to form an unionized or insoluble calcium salt. This removal of one of the end products prevents the reversal of the reaction and thus promotes a rapid splitting of the substrate. We adopted the use of the calcium ion, but in our work it was found that the chloride ion of calcium chloride, which was released with the formation of the calcium salt of the fatty acid, markedly reduced the pH of the medium, slowing down the reaction. To avoid this untoward effect, several calcium salts of weaker acids were tested. Calcium acetate was selected as the preferred salt to obtain the calcium ion effect of removal of one of the end products of the reaction and, at the same time, to promote good buffering. Balls, Matlack, and Tucker[16] reported that too much calcium chloride is somewhat inhibitory to this reaction. This effect was not related to lowering of the pH, as these authors maintained a fairly constant pH by the addition of ammonia. We found 0.2 Gm. of calcium acetate in 26 c.c. of solution to be the optimum amount for this reaction. This quantity provides for the fatty acid liberated by blood serum extraordinarily rich in lipase and at the same time does not have an inhibitory effect.

INACTIVATING THE ENZYME

Among the various methods of inactivating an enzyme, the two that are most convenient for an analytic method of this type are inactivation by heat and by alcohol. An important point, however, is that the control should be inactivated by the same method as the experimental. In some methods there exists the error of inactivating the control tubes containing the serum by heating and the experimental tubes containing the hydrolysate by addition of alcohol. The error that may occur from inactivating the same serum by the two methods is illustrated by Table IV.

TABLE IV

DIFFERENCE IN TITRATION VALUE OF SERUM ACCORDING TO METHOD OF INACTIVATION

SERUM	SUBSTRATE	METHOD OF INACTIVATION	C.C. OF 0.1 N KOH
Cat 3	----	Heating in Boiling H_2O	1.78
Cat 3	----	Addition of 100 c.c. of Alcohol-ether Mixture	2.25
Cat 2	Benzyl Butyrate	Heating in Boiling H_2O	1.48
Cat 2	Benzyl Butyrate	Addition of 100 c.c. of Alcohol-ether Mixture	2.47

The results of Table IV show the fallacy of inactivating the control tube by one method and the experimental by another method. The discrepancy exhibited in these data will account for a part of the values found in blood sera by the methods which use the two different procedures for inactivation.

Following the work of Balls, Matlack, and Tucker,[16] we have used a mixture of 9 volumes of 95 per cent alcohol and 1 volume of ether to inactivate both our experimental and control tubes. The alcohol, in addition to inactivating the lipase, provides an excellent medium for titration of the fatty acid released by the enzymatic hydrolysis, suppressing the dissociation of the hydroxyl ions in the mixture, and thus permitting the titration of the fatty acid.

TEMPERATURE AND INDICATOR

Balls, Matlack, and Tucker[16] have found that the optimum temperature for lipase action is around 40 to 50° C. We selected the temperature of 37° C. for our procedure because most laboratories usually keep a water bath at that temperature.

The indicator chosen for this work was phenolphthalein, since this indicator is suitable for titration of a weak acid with a strong base. It is of interest that the end point of this titration, as measured by the glass electrode, is at a pH around 10.2, which is higher on the pH scale than in an aqueous titration with phenolphthalein.

PROPOSED METHOD FOR LIPASE OR ESTERASE DETERMINATION

Reagents

1. *Glycerol-bile emulsifying reagent.*—(Balls, Matlack, and Tucker.) To 50 Gm. of dried oxbile (Bacto-oxgall, Difco Laboratories) in a liter Erlenmeyer flask add 50 c.c. of water. Heat this solution in an autoclave at 15 pounds pressure for two hours. Cool, add 500 c.c. of glycerol, and heat the mixture on a

steam bath until a clear solution is obtained. Keep in a stoppered flask in the ice box. When used, the flask is warmed in a water bath to 60 to 70° C. to facilitate pipetting.

2. *Buffer.*—Dissolve 5 Gm. of sodium diethylbarbiturate in 1 liter of solution.

3. *Calcium acetate solution.*—Dissolve 20 Gm. of calcium acetate, chemically pure $Ca(CH_3COO)_2 \cdot H_2O$, in 1 liter of solution.

4. *Alcohol-ether inactivating mixture.*—To 900 c.c. of 95 per cent ethyl alcohol add 100 c.c. of ether.

5. *Standard alkali.*—A 0.1 N alcoholic solution of potassium hydroxide is used.

Procedure

The Experimental.—Pipette the required amount of the substrate (0.25 c.c. of ethyl n-butyrate, tributyrin, benzyl n-butyrate, olive oil, or triolein) into a large eight-inch test tube. Into this tube are pipetted 5 c.c. of the bile-glycerol solution, previously heated in a water bath to 60 to 70° C. for convenience in pipetting. The tube is shaken, and then placed in boiling water for five to ten minutes, after which it is shaken again until the substrate is completely emulsified. After cooling to room temperature, pipette 10 c.c. of calcium acetate (200 mg.) and 10 c.c. of sodium diethylbarbiturate (50 mg.) into the tube. The tube is then placed in a water bath at 37° C., and when the mixture has reached the latter temperature, 1 c.c. of blood serum is pipetted into the tube and mixed thoroughly with the contents by means of a stirring rod. After the appropriate lapse of time (one hour for tributyrin, three hours for benzyl butyrate, twenty-four hours for olive oil, triolein, and ethyl butyrate), pour the contents of the tube into a 250 c.c. Erlenmeyer flask containing 100 c.c. of alcohol-ether mixture. Rinse the empty test tube with the alcohol-ether digestion mixture and pour the rinsings back into the Erlenmeyer flask. Add approximately 1 c.c. of 1 per cent phenolphthalein solution, and titrate with 0.1 N alcoholic potassium hydroxide to the same shade of pink as the blank. It is best to titrate to a deep permanent pink.

The Blank.—The blank tube is prepared and treated in exactly the same way, except that addition of the substrate is omitted. The substrate used should be neutral, and hence a correction for the omission of substrate in the blank is not needed.

Calculation.—Titration of experimental − titration of blank × 100 = units of lipase or esterase per 100 c.c. of serum.

We have redefined the lipase or esterase unit, and in agreement with conventional usage, have expressed results in terms of amount per 100 c.c. of serum. A unit of lipase or esterase is the amount of enzyme that will liberate 1 c.c. of 0.1 N fatty acid from an appropriate substrate at 37° C. in the time allowed (tributyrin, one hour; benzyl butyrate, three hours; ethyl butyrate, olive oil, triolein, twenty-four hours).

DISCUSSION

Using the improved conditions for enzyme activity which have been introduced into the above procedure, we obtain as high a titration in one hour's

hydrolysis of tributyrin by blood serum as is secured by twenty-four hours' hydrolysis of olive oil with the same serum. If tributyrin hydrolysis is as good a measure of the pathology present in pancreatic disease as olive oil hydrolysis, it would be a marked advance to use this one-hour test with tributyrin as substrate. To study this possibility, experiments with animals have been carried out and will be reported in another paper.[20] We may say here that in those experiments which were designed to simulate pancreatic pathology (pancreatic duct ligation, mecholyl stimulation, pancreatectomy), results obtained by the one-hour test with tributyrin as the substrate have reflected the condition present just as characteristically as when a 24-hour hydrolysis of olive oil was carried out. Chloroform poisoning, however, gave a dissociation of results: that is, an increase in the tributyrinase content of the serum without an increase in the values obtained with olive oil or triolein as substrates. Such results raise a question as to whether or not tributyrinase activity of serum might arise from liver injury as well as from pancreatic disease. The only way this question can be answered is by clinical trials. Our clinical studies thus far are too few to justify any conclusions at this time.

Following the above method with tributyrin as the substrate, we determined the lipase in the blood serum of a group of 30 apparently normal medical students. The values obtained ranged from 35 to 112 units per 100 c.c. of serum, showing a normal distribution curve with a peak at about 65 units. Nine of these values were obtained upon bloods collected in the morning about fifteen hours after food intake, and the remaining values are for bloods collected in the afternoon from individuals in the postabsorptive state about six hours. Some variation during the day appears to occur in the lipase content of blood serum, which, however, is not very marked. In our hands duplicate determinations with this method agreed within ±4.5 tributyrinase units per 100 c.c. of serum.

In all of our studies, a more rapid splitting of substrate was obtained with tributyrin than with the other four substrates used, namely, ethyl butyrate, benzyl butyrate, triolein, and olive oil. In explanation of this, it is suggested that the response measured with tributyrin represents the action of more than one enzyme; possibly tributyrin is attacked by "esterase" because of its short chain fatty acids, and at the same time is split by "lipase" since it is a triglyceride.

Since olive oil is a mixture of different glycerides and other substances and its composition may be expected to vary according to its source and methods of preparation, the use of this substrate in estimating "lipase" activity is to be questioned. For this reason we made parallel studies with a highly purified triolein* preparation as a substrate. The results obtained with triolein and olive oil as substrates, however, compare fairly closely, quantitatively, and have a similar significance in the studies made.

With the procedure outlined above, we have consistently found an enzyme in the blood of the normal dog, cat, rabbit, and human being which splits the lipids of olive oil. This observation is not in agreement with the work of Cherry and Crandall,[9] who did not find an enzyme in the blood of the normal dog which

*Kindly supplied to us by Dr. G. S. Jamieson of the Bureau of Agricultural Chemistry and Engineering, U. S. Dept. of Agriculture.

splits olive oil. We believe the inability of the Cherry and Crandall test to demonstrate the presence of an olive oil-splitting enzyme in normal dog serum is due to the lack of sensitivity of this method. In the latter procedure the hydrolysate is buffered to produce an initial pH of 7, which is below the optimum range for lipase; this feature would reduce considerably the rate of hydrolysis and could account for the failure to obtain splitting of olive oil by normal dog serum.

After our comparative studies were under way, it was realized that tributyrin could be dispersed without the aid of bile, since this glyceride is slightly soluble in water. Experiments showed that tribuytrin, when properly homogenized in the aqueous buffered digestion mixture, is split by blood serum even more rapidly than when emulsified with bile. It was necessary to use bile in our comparative studies for the satisfactory emulsification of the other substrates, and to make a true comparison, tributyrin had to be emulsified in the same way. Certain advantages are to be gained by using an aqueous tributyrin suspension, however. The end point of the titration with the aqueous suspension is more easily discerned, and the difficulty of preparing and titrating a bile emulsion is obviated. If bile is not used as the emulsifying agent for tributyrin, an equal volume of water is substituted and the test is carried out in the same way. This change in technique will yield values for normal blood serum about twice as high as those we obtained with the use of bile as the dispersing agent. We plan to report later normal values for human serum by this method when an aqueous tributyrin suspension is used.

The relation of the amount of fatty acid liberated to the concentration of enzyme and to the time of hydrolysis in the proposed method is of interest. As twenty-four hours of hydrolysis are required when ethyl butyrate or triolein or olive oil is used as the substrate, and three hours of hydrolysis are required with benzyl butyrate as substrate, studies of time or concentration relationships would be somewhat unsatisfactory with these substrates. The tributyrin procedure, however, is well adapted to such studies, since it requires only one hour of hydrolysis. The studies we made were with tributyrin as substrate, the procedure being the same as outlined above.

The results of these studies are shown in Figs. 1 and 2. Exact linear relationship of the amount of fatty acid liberated to the time of hydrolysis, or to the concentration of enzyme, is not shown. Fairly good relationships are present in the first three hours of hydrolysis, however; also where small amounts of enzyme (0.5 c.c. and 1 c.c. of serum) are used.

The amount of substrate used in these studies is a marked excess. The 0.25 c.c. of tributyrin is equivalent to 26 c.c. of 0.1 N butyric acid; the same amount of triolein is equivalent to 7.4 c.c. of 0.1 N oleic acid. These amounts of fatty acid are 25 to 30 times that liberated in a hydrolysis by the enzymes of normal human serum under the conditions of the method described. The pH at the end of the hydrolysis in the experiment represented by Fig. 1 was 7.3; in the experiment of Fig. 2 the pH at the end of three hours was 7.4. Both of these pH values are within the optimum range. The deviations from straight line relationships in Figs. 1 and 2 must therefore be attributed to other conditions than the amount of substrate or the buffering of the reaction.

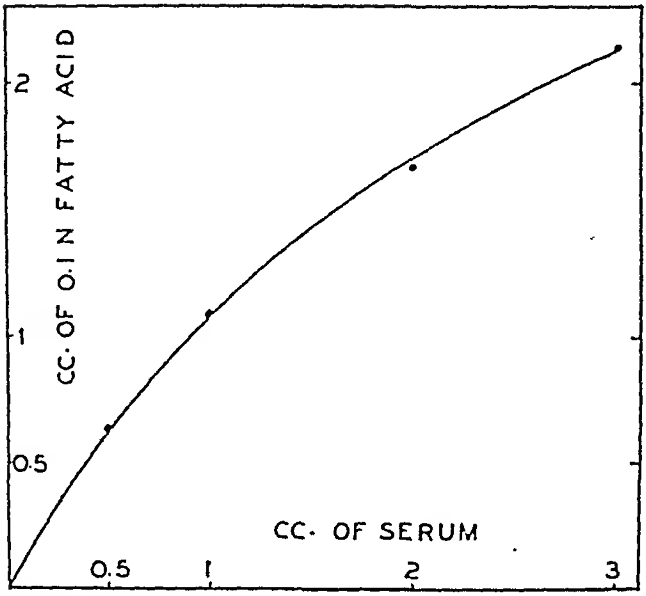

Fig. 1.—Relation of amount of fatty acid liberated to the concentration of enzyme under the conditions of the proposed method. Tributyrin was used as substrate, the time of hydrolysis being one hour. Human serum was the source of enzyme.

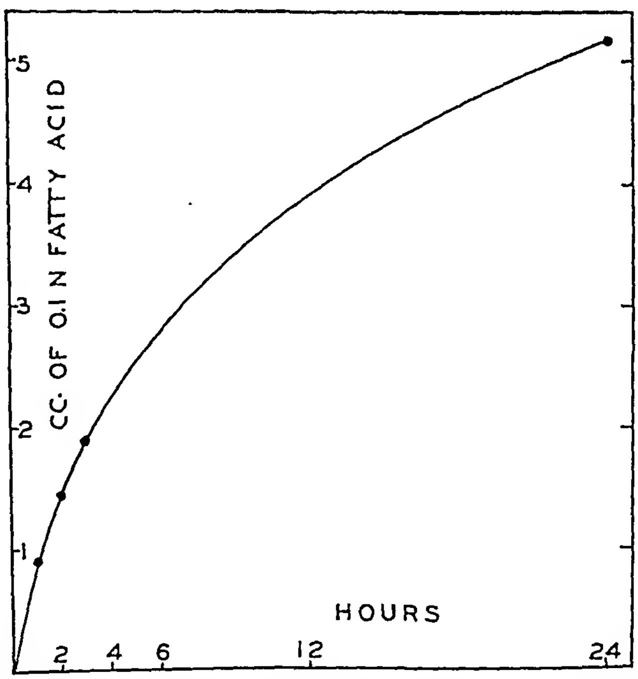

Fig. 2.—Relation of amount of fatty acid liberated to the time of hydrolysis under the conditions of the proposed method. Tributyrin was used as substrate, and cat serum was the source of enzyme.

SUMMARY

1. A study of the conditions entering into the determination of the lipidolytic enzymes of blood serum has been made. Attention was directed to the substrate, the emulsifying agent, the pH and suitable buffering, and the removal of end products.

2. In comparative studies of the five substrates, ethyl butyrate, tributyrin, benzyl butyrate, triolein, and olive oil, it was found that tributyrin is split most rapidly by the enzymes of blood serum.

3. A method for the estimation of the lipidolytic enzymes of blood serum is proposed. Using tributyrin as the substrate in this method, the amount of fatty acid liberated in one hour's hydrolysis by blood serum is comparable to the quantity obtained when a 24-hour hydrolysis of olive oil by the same serum is carried out.

4. This rapid test, involving a one-hour hydrolysis of tributyrin, may have clinical advantages. Further clinical work is necessary to appraise its possibilities.

A SIMPLE METHOD FOR THE APPROXIMATE ANALYSIS OF CARBON DIOXIDE AND OXYGEN IN GAS SAMPLES*

ALBERTA ILIFF, PH.D., GLADYS M. KINSMAN, PH.D.† ROBERT M. HILL, PH.D., AND ROBERT C. LEWIS, PH.D.
DENVER, COLO.

A SIMPLE apparatus which can be used by a relatively inexperienced technician to determine the carbon dioxide and oxygen content of samples of gas has been developed. The method of analysis is rapid and suitable for determinations where an accuracy of 0.3 per cent is adequate. This apparatus may be used for the determination of oxygen in samples of gas taken from cylinders containing mixtures of oxygen and nitrogen, and for the determination of carbon dioxide and oxygen in samples of gas collected from anesthetic apparatus, from oxygen tents, or from the thoracic cavity of patients with pneumothorax.

APPARATUS

The apparatus (Fig. 1) consists of a 10 c.c. burette calibrated in 0.05 c.c., on the top of which a stopcock (*A*) and a cup (*B*) have been annealed. It is advisable to have on hand at least two of these burettes in order that duplicate determinations can be made simultaneously.

The other pieces of equipment necessary to make the determinations consist of three 2,000 c.c. graduated cylinders, or hydrometer cylinders of similar size, in which the burettes may be completely immersed; three medicine droppers with fine capillary tips for filling the cups of the burettes and the rubber tubing connections; a ring stand equipped with a double spring burette clamp to support the burettes while introducing the solutions; a mouthpiece with a six-inch piece of rubber tubing attached to be used in filling the burettes with water; a 50 c.c. syringe and an appropriate needle for the collection of samples; and two short pieces (1.5 and 4 inches) of transparent rubber tubing and a screw clamp for use in the transfer of gas from the syringe to the burette or from a cylinder of oxygen and nitrogen directly to the burette.

CALIBRATION OF APPARATUS

In order to know the total amount of gas in the sample to be analyzed, it is necessary to determine the volume of the uncalibrated portion *C* (Fig. 1) of the burette between the zero mark and the stopcock *A*. This may be done by weighing the amount of water which the uncalibrated portion *C* of the burette will hold. To fill the burette, a short piece of rubber tubing and a mouthpiece, similar to that used with hematological pipettes, is attached to the capillary tip *D* below the stopcock *E*. The cup *B* is immersed in a beaker containing freshly

*From the Department of Biochemistry and the Child Research Council, University of Colorado School of Medicine.

†Formerly of this staff, now Professor of Nutrition, Department of Home Economics, University of Illinois, Urbana.

Received for publication, May 13, 1943.

boiled distilled water, which is drawn up by suction until the burette is completely filled. Care must be taken to prevent the presence of any air bubbles in the burette. Stopcocks *A* and *E* are closed, and the burette is placed in a burette clamp with the cup end up. Stopcock *A* is then opened, and, by careful control of stopcock *E*, just enough water is released so that the bore of stopcock *A* will contain air and the rest of the burette will be completely filled with water. The water is then discharged into a weighing bottle until the level of the liquid reaches the zero mark. The weight of the water and the temperature at which the weighing is made are recorded. An average of ten such weighings is corrected to the density of water at 25° C., and this value is used in the computation of the volume of the portion *C*.

The accuracy of the calibrations on the burette may be checked by the usual method of weighing the amount of water contained in each cubic centimeter.

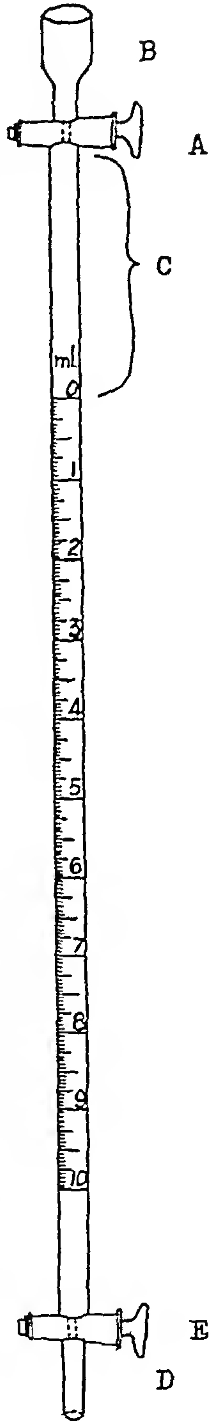

Fig. 1.—Diagram of burette used for the determination of carbon dioxide and oxygen in samples of gas. 1/3 actual size.

SOLUTIONS

A 15 per cent solution of either sodium or potassium hydroxide is used for the absorption of carbon dioxide. The potassium pyrogallate solution,[1] which is used for the absorption of oxygen, is prepared as follows: 450 Gm. of potassium hydroxide are dissolved in 300 c.c. of water, and, after complete solution has occurred, the liquid is thoroughly stirred, heated to boiling, and allowed to stand until it reaches room temperature. Then, 400 c.c. of this potassium hydroxide solution are added to 40 Gm. of pyrogallic acid in a 16 oz. widemouthed dark glass bottle. This is immediately stoppered, sealed with paraffin, and allowed to stand for a week before use. Since the solution keeps for two years or longer under these conditions, several bottles may be prepared at one time. When a bottle is opened for use, a rubber-stoppered washing bottle assembly is substituted for the original stopper. To prevent deterioration of the potassium pyrogallate between analyses, the ends of the glass tubing which project out through the stopper are protected from the air by medicine dropper bulbs. If care is thus taken to prevent undue exposure to air, this solution will keep in the washing bottle for at least nine months.

An oxygen absorbent,[2] which may be used immediately after it is made, consists of 16 Gm. of sodium hyposulfite, 13.3 Gm. of sodium hydroxide, 4 Gm. of anthraquinone β-sulfonic acid and 100 c.c. of water. When freshly prepared, it is just as satisfactory as the potassium pyrogallate. This alternate absorbent deteriorates rather rapidly, however,

even though it is protected from exposure to air by keeping it under mineral oil. Within one or two weeks a heavy precipitate develops during the analysis and thus prevents an accurate reading of the level of the solution.

COLLECTION OF GAS FOR ANALYSIS

The sample for analysis may be collected in a syringe and transferred to the burettes, or it may be taken directly into the burettes. The former procedure is used for the collection of pneumothorax air or of gas from an anesthetic apparatus; the latter, for the collection of air from an oxygen tent or from a tank containing a mixture of nitrogen and oxygen.

When a sample of pneumothorax air for duplicate analysis is to be collected, a sterile needle and a sterile 50 c.c. syringe must be used. The needle and the tip of the syringe are filled by drawing 1 or 2 c.c. of sterile water into the syringe, expelling any air bubbles that may have been admitted, and then emptying the syringe of water. The needle and the tip of the syringe are thus left filled with sterile water. The needle is inserted into the chest wall, and air is drawn into the syringe. After the needle is withdrawn, it is quickly removed from the syringe and a short piece of transparent rubber tubing, which has previously been clamped in the middle and completely filled with water, is immediately slipped onto the tip of the syringe. The transparency of the tubing permits one to be sure that no contaminating air bubbles have been admitted. After filling the burette with water in the manner described under the directions for its calibration, the unattached end of the rubber tubing, which should still be filled with water, is carefully slipped over the capillary tip *D*. Again care must be taken to exclude all air bubbles. The clamp on the rubber tubing is released and both stopcocks of the burette are opened while the cup end is held lower than the syringe. By pressing lightly on the plunger of the syringe, a sample of gas is transferred to the burette. When only about 4 c.c. of water remain in the burette, stopcock *A* and then stopcock *E* are closed. The tubing is clamped off and then removed from the burette. After again filling the free end of the tubing with water, a duplicate sample is transferred from the syringe to a second burette.

When gas from an anesthetic apparatus is to be collected, the needle and syringe need not be sterilized. The needle and the tip of the syringe are filled with water, and a sample of air is secured by inserting the needle in one of the rubber tubing connections. From this point, the procedure for transferring the gas to the burettes is the same as that described for pneumothorax air.

Air from an oxygen tent is collected directly into the burette. After the burette has been completely filled with water, the stopcock *E* is opened, and this end of the burette is inserted through the armhole of the tent to a point about midway between the face of the patient and the front wall of the tent. The burette is held at an angle of about 45 degrees, and the air sample is collected by permitting the water to run out of the lower stopcock *A* until about 4 c.c. remain. Stopcock *E* is closed as the burette is being withdrawn from the tent. In a similar manner, a duplicate sample is collected in a second burette.

In sampling gas from a tank containing a mixture of nitrogen and oxygen, a four-inch piece of transparent rubber tubing is connected to the outlet of the

tank. Room air is washed out of the valve of the tank by gently releasing gas for five or six seconds. The rubber tubing and the burette are completely filled with water, and the free end of the tubing is connected to the burette at tip *D*. If care is taken, this may be done without the introduction of room air. After opening stopcocks *A* and *E*, all but about 4 c.c. of water are forced out of the burette by a gentle stream of gas. The valve of the tank is shut off and the burette is disconnected after both stopcocks have been closed. In the same way a duplicate sample of gas is collected in a second burette.

PROCEDURE FOR ANALYSIS

The burettes containing the duplicate samples of gas are placed in the clamps with the cup ends uppermost. Approximately 2 c.c. of water are introduced into each cup with a medicine dropper. The upper stopcock of each burette is opened, and the lower stopcock *E* is then cautiously turned to permit enough water to run out to fill the capillary tip *D* with water. The lower stopcock must be closed while sufficient water remains in cup *B* to prevent the entrance of room air into the sample. After removing the excess water from the cup with a medicine dropper, the lower stopcock *E* of the burette is immersed in the water which almost fills the first graduated cylinder; the stopcock is opened; and the burette is lowered into the cylinder so that the entire burette up to the cup is covered with water. The two burettes are thus left in the water for two minutes in order that the gas may attain the same temperature as that of the water. In turn, each burette is lifted by the cup to prevent heating of the gas by the warmth of the hand, the exposed part is dried off with cheesecloth, and the height of the burette is adjusted so that the level of the water inside the burette is the same as that in the cylinder. The top (outer border) of the meniscus is read, because the bottom of the meniscus cannot be clearly distinguished later in the analysis after potassium pyrogallate is added. After the burette is read, the lower stopcock *E* is closed under water; the burette is withdrawn and again placed in the burette clamp. The second burette is handled in a similar manner. Approximately 2 c.c. of the potassium hydroxide solution are now admitted into each burette in the same way as the water was introduced. The burettes are removed from the clamps and inverted twice to assure contact of the gas with the potassium hydroxide. The burettes are then placed in the second graduated cylinder, and, after permitting all of the solution in each to drain to the lower end, readings are made as previously described. The burettes are removed, again inverted, returned to the graduated cylinder, and read a second time. If the two readings do not check within 0.02 c.c., the process is repeated. The difference between the initial and the final reading multiplied by 100 and divided by the sum of the initial reading and the volume of the uncalibrated portion *C* of the burette gives the per cent of carbon dioxide in the sample.

When check readings for carbon dioxide have been obtained, about 2 c.c. of potassium pyrogallate solution are blown into the cup of each burette from a bottle of this reagent that has been fitted with a washing bottle assembly. The pyrogallate is admitted to the burettes in the same manner as described for the

other solutions. The burettes are inverted twice, placed in the third graduated cylinder, and read as previously described. The process of inversion and reading is repeated until no change greater than 0.02 c.c. occurs in either burette on successive readings. The per cent of oxygen in the sample is calculated by taking the difference between the final reading for carbon dioxide and the final reading for oxygen, multiplying this difference by 100, and dividing by the sum of the initial reading (before the absorption of any gas has taken place) and the volume of the uncalibrated portion *C* of the burette.

When the analysis is completed, the burettes are thoroughly rinsed until the wash water no longer gives an alkaline reaction to litmus paper. Further analyses may be made immediately. From twenty to twenty-five minutes are required for making duplicate analyses and for washing the burettes in preparation for the next determination. If only one pair of duplicate analyses is to be made, just one cylinder needs to be used, since the loss of solutions into the water will not impair the accuracy of the next step in the determination. When the analyses for the day are completed, the stopcocks of the burettes are carefully greased and the cylinders are washed and filled with water, so that the air in the water will be lost by the time the next determinations are to be made.

ACCURACY OF THE METHOD

Table I gives results of analyses obtained on several different types of determinations and shows the variation to be expected by this method of analysis. It may be seen that the variation observed between duplicate analyses is not greater than 0.35 per cent. As a further check on the method, air from an open circuit chamber procedure for the determination of basal metabolism[3] has been analyzed both with the Carpenter-Haldane gas analysis apparatus[4] and with the procedure herein reported. Table II gives the results of 21 such analyses. The values found for carbon dioxide and for oxygen with the apparatus described check within 0.5 per cent of one another, and the mean values are within ±0.3 per cent of those obtained with the Carpenter-Haldane apparatus. It is evident from the results reported in Tables I and II that the method of analysis is suitable for determinations where an accuracy of 0.3 per cent is adequate.

ADVANTAGES OF THE METHOD

Some of the advantages of the procedure described are listed as follows: (a) The apparatus can be made with ordinary laboratory equipment by any competent glassblower;* (b) the method is suitable for the analysis of gas containing carbon dioxide and oxygen in widely divergent concentrations; (c) regardless of the time elapsed since the last determination, the apparatus is ready for immediate use without the necessity of cleaning capillary tubing or of making a preliminary test for leaks as would be essential with many types of apparatus for gas analysis; (d) only from twenty to twenty-five minutes are required to make duplicate analyses; (e) after relatively little practice accurate results can be obtained by a technician who has had no previous experience in gas analysis.

SUMMARY

1. An apparatus and a method for the determination of carbon dioxide and oxygen, or both, in samples of gas are described.

2. The method is easy to use and duplicate analyses can be made in from twenty to twenty-five minutes.

3. The apparatus is ready for immediate use regardless of the time elapsed since the last determination.

4. The method is very satisfactory for determinations in which an accuracy of 0.3 per cent is sufficient.

5. The apparatus is valuable for making determinations of samples of gas taken from cylinders containing mixtures of oxygen and nitrogen, from anesthetic apparatus, from oxygen tents, or from the thoracic cavity of patients with pneumothorax.

*If the expense involved is not a matter of consideration, an apparatus with the zero mark of the burette at stopcock *A* may be substituted for the one herein described. The only advantage of such a refinement would be that the total volume could be read directly; the accuracy of the apparatus would be in no way enhanced.

THE ESTIMATION OF THE ENZYMES, AMYLASE, PROTEINASE, AND LIPASE IN DUODENAL CONTENTS*

ALFRED H. FREE, PH.D., AND VICTOR C. MYERS, PH.D., D.SC.
CLEVELAND, OHIO

SOON after the introduction of the duodenal tube as a successful method for obtaining duodenal contents, studies of the enzyme activities of this material were made. A variety of methods utilizing various chemical principles have been employed in such studies. In 1934 a committee appointed by the American Gastroenterological Association[1] conducted a study of the methods used to determine the enzyme activities of duodenal contents. A report of this committee stated: "It is obvious that this survey denoted the existence of unsolved technical difficulties in pancreatic enzyme analysis, otherwise there would be more unanimity of opinion favoring one system of tests. There is insufficient proof at the present time that we have a system of tests which is sufficiently accurate and simple to be routinely adopted for clinical purposes." The clinical usefulness of such enzyme studies has been recently reviewed.[2-4] The present investigation was undertaken to devise a system of enzyme methods that would employ optimal environmental conditions, would be applicable to use in a routine clinical biochemical laboratory, and could be readily evaluated by the clinician.

METHOD OF OBTAINING AND DILUTING DUODENAL CONTENTS

Duodenal contents may be readily obtained by means of a duodenal tube. The authors have made studies of the activities of fasting contents and contents obtained after stimulation of pancreatic secretion with olive oil introduced into the duodenum.[5, 6] Other investigators have utilized fasting contents[7] as well as contents obtained after using a variety of stimulants including magnesium sulfate, dilute hydrochloric acid, peptone solution, corn oil, olive oil, cream, beef bouillon, secretin,[8-12] and mecholyl.[11]

The sample to be analyzed is refrigerated between the time of obtaining from the patient and the time the analyses are to be made. Repeated studies have indicated that there is no significant alteration in enzyme activity of duodenal contents during a period of twenty-four hours, provided the sample is not strongly acid due to contamination with gastric juice. In such cases the results are quite unreliable even though the analyses are made immediately. One c.c. of the sample is made up to a volume of 50 c.c. by adding 10 c.c. of 0.2 molar phosphate buffer (pH 7.2) and distilled water. The 1:50 diluted sample is added to 9.5 c.c. of 0.2 molar phosphate buffer (pH 7.2) to give a

*From the Department of Biochemistry, School of Medicine, Western Reserve University. The data presented in this paper are in part taken from the dissertation submitted by Alfred H. Free to the Graduate School of Western Reserve University, June, 1939, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

Received for publication, July 2, 1943.

1:1,000 dilution. This dilution is used for the determination of amylase. It is important to make the dilution with the buffer rather than with distilled water, since marked destruction of amylase may occur when samples are diluted with distilled water.

REAGENTS

1. *General Reagent*

A. 0.2 molar phosphate buffer, pH 7.2, prepared by dissolving 7.62 Gm. of anhydrous potassium dihydrogen phosphate and 20.45 Gm. of anhydrous disodium hydrogen phosphate in water to give a total volume of 1 liter.

2. *Reagents for Amylase*

A. One per cent soluble starch solution, prepared by suspending 1 Gm. of soluble starch (Merck, according to Lintner) in about 5 c.c. of cold water and then pouring about 90 c.c. of boiling water into the suspension. This solution is boiled for exactly one minute and then made up to a volume of 100 c.c. This solution should be refrigerated and should be prepared fresh approximately every two weeks. Even after standing in the refrigerator for a period of about three days the starch solution acquires a turbidity. If the flask containing the solution is heated for a minute in a boiling water bath, however, the turbidity will disappear and the digestibility of the solution will be the same as a freshly prepared solution.

B. Standard glucose solution which is a saturated solution of picric acid containing 1 mg. of glucose in each 3 c.c. of solution.

C. 0.5 molar sodium chloride solution.

D. Saturated solution of sodium carbonate.

3. *Reagents for Proteinase*

A. Five per cent casein solution, prepared by suspending 5 Gm. of casein (Merck, according to Hammarsten) in about 50 c.c. of water and then adding 40 c.c. of 0.1 normal NaOH and sufficient water to make a total of 100 c.c. This solution should be refrigerated and should be prepared fresh about every two weeks.

B. Twenty per cent solution of trichloro-acetic acid.

C. Nessler's solution prepared by method of Folin.[13]

D. Digestion mixture for micro-Kjeldahl determination consisting of 50 per cent sulfuric acid containing 0.25 per cent copper sulfate.

E. 0.3 per cent gum ghatti solution, used for micro-Kjeldahl determination.

F. Nitrogen standard containing 0.283 Gm. of ammonium sulfate per liter (0.3 mg. of nitrogen in 5 c.c.).

G. Standard tyrosine solution containing 0.15 mg. of tyrosine in 3 c.c. Method of preparation described by Anson and Mirsky.[15]

H. Phenol reagent of Folin and Ciocalteau.[14]

I. 0.5 N sodium hydroxide solution.

(Solutions C, D, E, and F are needed only if the micro-Kjeldahl determination of nonprotein nitrogen is employed in the proteinase method.)

4. *Reagents for Lipase*

A. One per cent bile salt solution, prepared by dissolving 1 Gm. of bile salts (Wilson Laboratories, Chicago) in 100 c.c. of water. This solution should be refrigerated, and should be prepared fresh approximately every two weeks.

B. 0.1 normal sodium hydroxide in alcohol, prepared by adding sufficient saturated solution of sodium hydroxide to 95 per cent alcohol to give a 0.1 normal solution. The base is standardized against 0.1 normal acid in the conventional manner.

C. Tributyrin, obtained from Eastman Kodak Co., Rochester, New York.

METHOD FOR DETERMINATION OF AMYLASE

The principle of the method for the determination of amylase is based on the measurement of the amount of reducing sugar formed when a sample of diluted duodenal contents is incubated with a solution of soluble starch. Under proper environmental conditions, the amount of reducing sugar formed is proportional to the amount of amylase present so that this figure furnishes an index of the enzyme concentration.

Add 6 c.c. of 1 per cent soluble starch to a test tube along with 1 c.c. of 0.5 molar sodium chloride and 2 c.c. of phosphate buffer (pH 7.2 to 0.2 M). This mixture is warmed to 38° C. in a constant temperature water bath or a constant temperature oven and then 1 c.c. of the 1:1,000 diluted duodenal contents is added. The tube is thoroughly mixed and replaced in the water bath for exactly thirty minutes. At the end of this time a small amount of dry solid picric acid (about 0.5 Gm.) is added and the contents of the tube saturated with picric acid by continued mixing. This effectively stops enzyme action and provides a saturated picric acid solution for the determination of reducing sugar. Three c.c. of the supernatant solution are pipetted into a Myers-Bailey sugar tube, and 1 c.c. of saturated sodium carbonate solution is added. A standard is prepared by taking 3 c.c. of the glucose standard in picric acid and adding to it 1 c.c. of the saturated sodium carbonate solution. The tubes are placed in a boiling water bath for exactly twenty minutes to effect color development. The standard is diluted to 10 c.c. and the unknown to either 10, 15, or 20 c.c., following which the solutions are compared in a colorimeter. The equivalent of glucose which is produced in the digestion is calculated by the equation $S/R \times D/10 \times 1.0 \times 10/3 =$ mg. of glucose equivalent. A blank which represents the reducing action of the starch must be determined and subtracted from the above value. This will be quite constant for a given batch of starch solution on any particular day and can be readily determined by carrying through the entire procedure described above for the digestion mixture with the exception that the diluted duodenal contents are not added to the reaction mixture until after the precipitation with picric acid. Since all of the reducing value of the blank is contributed by the starch solution, one blank is sufficient for a series of determinations.

METHOD FOR THE DETERMINATION OF PROTEINASE

Proteinase is determined by incubating diluted duodenal contents with a solution of casein and then determining the amount of protein digestion products formed. The index of proteinase concentration is taken as the amount of nonprotein nitrogen formed from the casein or as the amount of material formed which will react with the phenol reagent.

Three c.c. of casein solution are added to a test tube along with 3 c.c. of water and 3 c.c. of phosphate buffer (pH 7.2 to 0.2 M). The test tube is placed in the constant temperature water bath at 38° and allowed to reach equilibrium temperature. To the tube is now added 1 c.c. of 1:50 diluted duodenal contents and the mixture thoroughly stirred. The tube is replaced in the bath and digestion is allowed to proceed for exactly thirty minutes, at the end of which time the tube is removed and 2 c.c. of 20 per cent trichloro-acetic acid are added. This serves to stop the enzyme action as well as to precipitate the undigested casein. The solution is filtered and either a 1 c.c. or a 2 c.c. aliquot is used for a nitrogen determination according to the micro-Kjeldahl procedure described later, or a 1, 2, or 3 c.c. aliquot is used for the colorimetric phenol reaction described later. A choice of either of these methods is offered depending on the facilities of the laboratory, since it has been found as a result of several hundred analyses that the two methods give the same results. It is the authors' belief that if the laboratory routinely carries out determinations of nonprotein nitrogen on blood the micro-Kjeldahl nitrogen estimation might be the method of choice whereas otherwise the colorimetric phenol determination would be more convenient.

For the determination of nonprotein nitrogen the following procedure is employed: An aliquot of filtrate is placed in a large Pyrex test tube calibrated at 35 c.c. and 50 c.c. One cubic centimeter of sulfuric acid digestion mixture is added along with a glass bead, and the mixture is digested over a flame or on a hot plate until perfectly colorless. Two or three drops of superoxol are added at intervals to facilitate the digestion. The digestion material is cooled, some water and 1 c.c. of gum ghatti solution are added, and the solution made up to 35 c.c. A standard is prepared in the following manner: Five c.c. of standard nitrogen solution are measured into a similar tube, 1 c.c. of the digestion mixture added along with 1 c.c. of gum ghatti and diluted to 35 c.c. Fifteen c.c. of dilute Nessler's solution (Folin) are added to both the unknown and the standard, and the colors are compared in a colorimeter. The calculations are based on the formula: $S/R \times 12/A \times 0.3 =$ mg. of nitrogen produced in the digestion. A is the volume of the aliquot used for the nitrogen determination.

Casein solutions prepared according to the above method contain small amounts of nonprotein nitrogenous substances. Correction for this is made by running a blank digestion in exactly the same manner as described above with the exception that the diluted duodenal contents are added after the precipitation with trichloro-acetic acid. This is filtered, and the nitrogen is determined in the filtrate according to the method described. One blank is sufficient for a series of determinations, and this blank value is subtracted from the total nonprotein nitrogen.

If the proteinase activity is to be determined by the colorimetric phenol reaction, the following procedure is employed: Three c.c. of the trichloro-acetic acid filtrate are measured into a test tube, to which are added 6 c.c. of 0.5 N NaOH and 2 c.c. of diluted phenol reagent diluted 1 to 3 with distilled water just before using. A blue color develops spontaneously; this should be compared after ten minutes with a standard solution of tyrosine. The stand-

ard is prepared by treating 3 c.c. of tyrosine standard with sodium hydroxide and phenol reagent in the same manner as the filtrate. Where the amount of proteinase activity is relatively large, the color of the unknown will be considerably darker than that of the standard and will thus result in a certain error due to the disproportionality of the colors. In this case the use of a 1 c.c. aliquot of filtrate is necessary. In order to make the final volume the same, as well as to secure the proper reaction, 2 c.c. of a mixture of phosphate buffer, trichloro-acetic acid, and water in the proportion in which they occur in the filtrate are added to the tube containing the 1 c.c. aliquot. This is then made alkaline, and the color is developed in the usual manner. If this is done, the proportionality of enzyme concentration to the intensity of color developed will hold. Of course, the use of a smaller amount of filtrate must be taken into account in the calculations. The calculation of the amount of proteinase activity may be made by the following formula: $S/R \times 12/A \times 0.15 =$ mg. of tyrosine equivalent produced in the digestion.

A blank determination is necessary, since the casein solution will yield a filtrate after precipitation that contains a small quantity of substances which react with the phenol reagent. The blank is prepared according to the method described above, and the filtrate is then subjected to the same treatment which is given to the digest filtrate. The value of the blank is subtracted from the value obtained in the digestion mixture.

METHOD FOR THE DETERMINATION OF LIPASE

Lipase is determined by incubating duodenal contents with tributyrin and then titrating the amount of acid liberated. The index of lipase concentration is calculated from the amount of acid released.

Into a 200 mm. test tube are measured 4 c.c. of phosphate buffer, 1 c.c. of 1 per cent solution of bile salts, and 5 c.c. of 1:50 diluted duodenal contents. The tube is warmed for three or four minutes in the constant temperature bath at 38° C. One c.c. of tributyrin is then added, and the contents of the tube are thoroughly agitated. The agitation of the tube at this point is important, since it is responsible for the formation of a semiemulsion which is required for the reaction. The tube is replaced in the constant temperature bath and enzyme action is allowed to proceed for one hour, during which time the temperature of the bath is maintained at 38° C. At the end of this time the tube is removed, and 5 c.c. of alcohol and a few drops of phenolphthalein are added. The contents are then immediately titrated with 0.1 N NaOH in 95 per cent alcohol to the first color change of the phenolphthalein.

Since phosphate buffer is present, there will be a small blank titration even though no lipase digestion has occurred. This amounts to approximately 2.75 to 3.00 c.c. of 0.1 N alcoholic NaOH. When this blank is subtracted from the titration, the resulting value gives a measure of the lipase activity. Since the blank is entirely due to the phosphate buffer and tributyrin, one blank will suffice for a series of determinations.

With the environment described for the lipase estimation, the relation between the amount of acid liberated and the amount of enzyme present is not linear. Therefore, it is necessary either to prepare a graph and read the values from the graph or to use a table and obtain the values from the table.

This, although somewhat troublesome, does not impair the accuracy of the final results obtained by this method.

VARIATIONS OF ENZYME ACTIVITY WITH VARYING ENZYME CONCENTRATION

In both the amylase and proteinase method there is a linear relation between the index of enzyme activity and the enzyme concentration over the range of values encountered in normal and abnormal samples of human duodenal contents. This relation is shown in Figs. 1 and 2. Therefore, in the case of amylase determinations, the amount of reducing sugar produced by the digestion can be used as an index of enzyme concentration. Similarly in the proteinase determination the amount of nonprotein nitrogen liberated from the casein or the amount of tyrosine-like material liberated can be used as an index of enzyme concentration. In the lipase method, however, there is not a direct linear relation between the amount of enzyme present and the amount of acid liberated. The curve for the variation of acid liberated with variations in enzyme concentration is shown in Fig. 3. Therefore, in order to secure an accurate index of lipase concentration, it becomes necessary to use the curve or to employ a table such as that indicated by Table I.

STUDIES OF FACTORS INFLUENCING ENZYME ACTIVITY

Many of the steps in carrying out determinations of enzymes are quite arbitrary, since the methods for enzyme measurement are based on determination of enzyme activity. By variation of each of the arbitrary steps in the procedure it is possible to obtain a method which estimates the enzyme under optimal environmental conditions. Fig. 4 shows the effect of variations in pH on the activity of amylase in duodenal contents. It will be seen that when the digestion mixture is buffered with phosphate buffer of pH 7.2, there is an optimal conversion of starch to reducing sugar. Therefore, this pH was employed in the amylase determination. Since optimal digestion by proteinase and lipase also occurs at this reaction, the same buffer is used in the procedure for the estimation of proteinase and lipase. A complete description of the experimental studies that have been carried out in the development of the methods here described has been reported elsewhere.[16] It should be stated that not only is the pH optimal, but also the substrate concentration, buffer concentration, salt concentration, and the amount of duodenal contents employed are optimal for the methods described.

ENZYME ACTIVITIES OF DUODENAL CONTENTS OF NORMAL SUBJECTS

When fractional samples of duodenal contents are obtained after stimulation of pancreatic secretion with olive oil, there is a considerable variation in the enzyme activity of various fractional samples. For this reason the maximum enzyme concentration of the fractional samples has been selected as a more constant criterion of potential enzyme activity.[6] The maximum amylase, proteinase, and lipase values obtained in 17 studies made on 11 normal subjects are shown in the first three columns of Table II. The average maximum enzyme activities for these normal subjects are amylase, 10.99 mg. of glucose equivalent; proteinase, 2.24 mg. of tyrosine equivalent; and lipase, 13.92 c.c. of 0.1 N acid liberated (uncorrected).

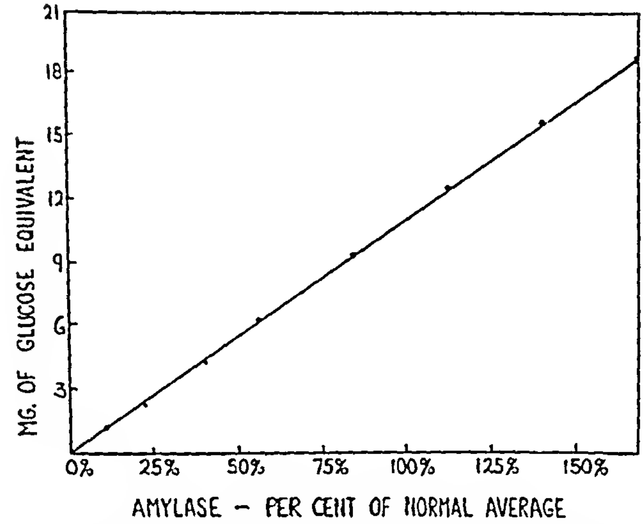

Fig. 1.—Relation of amylase activity to amylase concentration. The variations in enzyme concentration were attained by using different amounts of the same sample of duodenal contents. For convenience the various concentrations are expressed as a per cent of the normal average. Amylase activity is expressed as mg. of glucose equivalent formed in the digestion mixture.

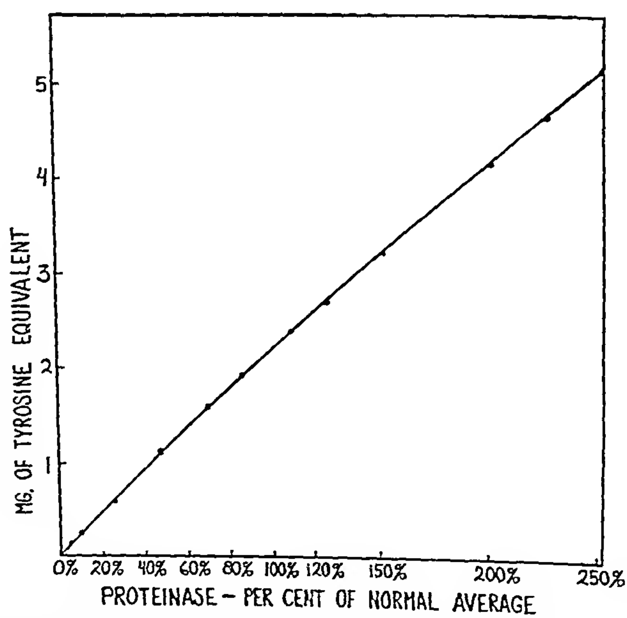

Fig. 2.—Relation of proteinase activity to proteinase concentration. The variations in enzyme concentration were attained by using different amounts of the same sample of duodenal contents. For convenience the various concentrations are expressed as a per cent of the normal average. Proteinase activity is expressed as mg. of tyrosine equivalent formed in the digestion mixture.

The authors have proposed a simplified method of expressing enzyme values.[4-6] According to this system any individual finding is expressed as a percentage of the normal average value. On this basis the values for the normal subjects are shown in the last three columns of Table II. The conversion of amylase or proteinase figures to this system is quite simple and merely involves multiplying by a factor. The factor for the conversion of mg. of glucose equivalent to amylase as a per cent of the normal average is 9.1. For proteinase determined from the tyrosine reaction one needs to multiply the mg. of tyrosine equivalent by the factor 44.4. If the amount of nonprotein nitrogen formed by the proteinase is measured (the average amount of nonprotein nitrogen obtained in the normal subjects is 4.70 mg.), the factor is 21.3. The values for lipase as a per cent of the normal average can be approximated from the data given in Table I or from Fig. 3.

Using this method of comparison the range of variation of amylase is from 55 per cent to 165 per cent of the average normal, whereas proteinase varies from 45 per cent to 148 per cent while lipase varies from 46 per cent to 147 per cent. In the subjects in whom more than one study was made there was considerable variation in the maximum enzyme concentration, but this variation was less than that observed in the different subjects.

This system of expressing results of enzyme studies as a per cent of the normal average can also very readily be applied to results obtained in patients as has been done by the authors.[6] It thus greatly facilitates the clinical interpretation of such data. This method is quite logical, since enzyme measurements determine relative rather than absolute concentrations, the relative concentration being derived from the activity of the enzyme.

DISCUSSION

It should be pointed out that the principles of the methods that are described above are not new. In certain respects the amylase determination makes use of the same principles employed by Myers and Killian[17] in the determination of blood amylase or diastase. Picric acid reduction is particularly well adapted for the measurement of the substances resulting from starch digestion, since maltose, which is the principal product of amylolysis, exerts approximately twice the reducing effect on picric acid that it does on most copper reagents.[18] The use of sodium chloride in the digestion mixture enhances the activity of the amylase and removes the possibility that with some samples the chloride content might influence the measured amylase activity. The use of a pH of 7.2 gives a much greater activity than that obtained at other reactions, such as the pH of 8.4 employed by McClure, Wetmore, and Reynolds.[19] This is clearly demonstrated in Fig. 4.

The proteinase method is in certain respects patterned after the proteinase methods of McClure, Wetmore, and Reynolds,[19] and Anson and Mirsky.[15] The latter investigators employed hemoglobin as a substrate and maintained that this is the only reproducible substrate for proteinase estimations. The reproducibility of casein as employed in the proteinase method has been carefully investigated by means of an experiment in which several different batch preparations of Merck's Casein, according to Hammarsten, were obtained and were used as substrates with the same sample of duodenal contents as a source of enzyme.

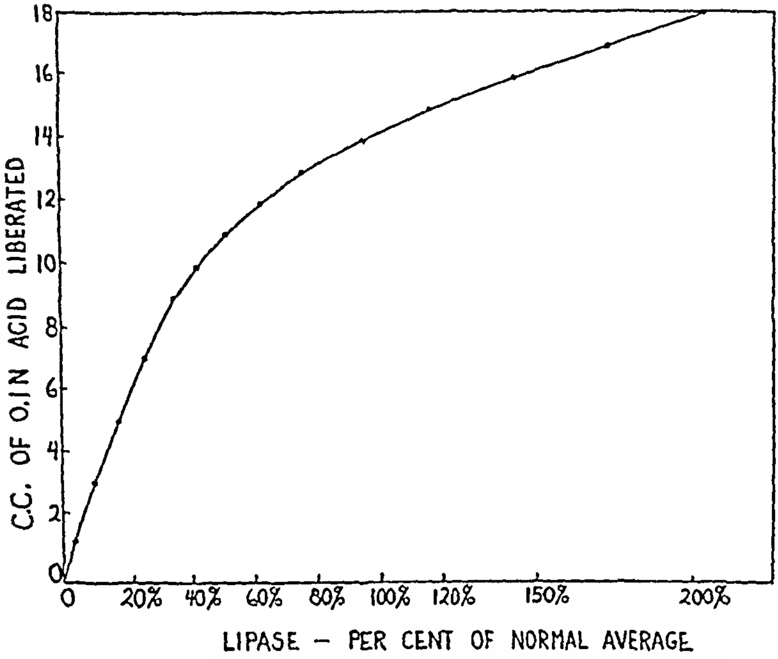

Fig. 3.—Relation of lipase activity to lipase concentration. The variations in enzyme concentration were attained by using different amounts of the same sample of duodenal contents. For convenience the various concentrations are expressed as a per cent of the normal average. Lipase activity is expressed as the c.c. of 0.1N acid liberated in the digestion mixture.

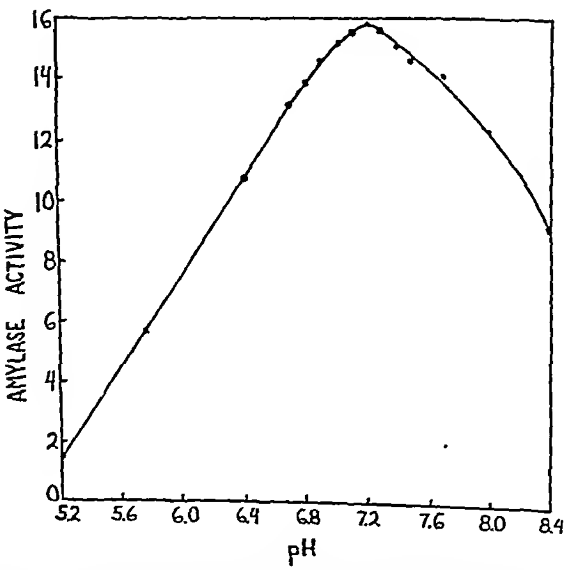

Fig. 4.—Effect of pH on amylase activity. Variations in pH were accomplished by varying the ratio of the acidic and basic salt in the phosphate buffer. All other factors were maintained constant.

The values obtained with the different samples of casein were identical. A sample of casein prepared in the laboratory by a comparable technique also gave a satisfactory result. Experimental data also indicated that a casein solution prepared by the described technique could be used for as long as three weeks without any change in digestibility, although during this time there was some increase in the value of the blank.

The lipase method employs the same principle that has been made use of in a large number of methods of lipase estimation. In most of these methods the amount of acid liberated by the hydrolysis of a substrate catalyzed by lipase has been measured. Chace and Myers[20] used ethyl butyrate as a substrate; McClure, Wetmore, and Reynolds[19] employed cotton seed oil; Wads-

worth and Aaron[21] utilized triacetin; and Cherry and Crandall[22] used olive oil emulsion. There have been several objections raised to the use of tributyrin[22] as a substrate for lipase estimations, since it has been maintained that the digestion of tributyrin is accomplished by an esterase and not by the lipase involved in the splitting of higher fats. In a series of approximately 500 determinations in various normal and abnormal samples of duodenal contents by the method described above, parallel determinations of lipase by a method quite similar to that described were made in which the substrate was an olive oil emulsion. In every one of the samples studied the amounts of acid liberated from tributyrin and from olive oil emulsion were practically identical. In no instance would the clinical interpretation of the finding be any different whether olive oil or tributyrin was used. Since tributyrin is somewhat more convenient to obtain and handle, the method using tributyrin is preferred by the authors to the method using olive oil emulsion. The addition of bile salts to the digestion mixture is designed to eliminate any effect the amount of bile in a sample of duodenal contents might have on lipase activity.

Intestinal contents obtained by means of a Miller-Abbott tube from an isolated segment of intestine[23] have been studied in an endeavor to ascertain whether intestinal secretions when uncontaminated with pancreatic juice possess any enzymes that will give appreciable enzyme activity under the environmental conditions described in the above methods. Intestinal secretions obtained from two normal human subjects did not show any appreciable enzyme activity by the methods described. This would indicate that alteration in the enzyme concentrations of duodenal contents are entirely due to variations in the enzyme concentration of the pancreatic juice or variations in the amount of pancreatic juice in relation to the total volume of duodenal contents.

There is a considerable range of variation in the enzyme activity of duodenal contents of normal human subjects. This makes the definition of the pathologic values quite difficult. By a combination of factors we believe that we are able to define more accurately the normal variations and thus obtain an earlier recognition of pathologic values. These factors include: (1) the use of sensitive accurate enzyme methods; (2) the elimination of certain variability of pancreatic secretory activity by using the maximum enzyme activity of fractional samples; and (3) the expression of the values by a convenient system which permits evaluation on the basis of the normal average. This has been demonstrated by data on a group of fifteen miscellaneous cases, given in Table V of the paper,[6] presenting observations obtained with these methods.

SUMMARY

Methods are described for the estimation of the enzymes of the duodenal contents, amylase, proteinase, and lipase, in which an optimum pH and optimum concentrations of substrate, buffer, and salt are employed. The values for the enzyme activities are recorded in terms of the normal taken as 100, and thus permit ready interpretation by the clinician.

MEDICAL ILLUSTRATION

NEW IMPROVEMENTS IN MOULAGE PROSTHESIS*

CARL D. CLARKE,† PH.D., WASHINGTON, D. C.

THE word *prosthesis* means an artificial organ, such as an eye, nose, ear, hand, leg, or denture that is used to replace an absent part in the body.

In reprinting one of my articles entitled *Moulage Prosthesis,* the editor of the publication changed the title to *Facial Prosthesis.* This was undoubtedly done for clarification because the word *moulage* is not fully understood. Any author working on the subject of molding and casting is plagued with the necessity for the continued use of these two words. Sometimes he varies them with positive and negative. The word *moulage* has come to be known by a select few in the medical sciences as a wax cast. There are, however, more durable and lifelike mediums than wax. Wax is rapidly becoming a substance for admixing with other ingredients to produce an intermediate stage, pattern, or model in the molding and casting art. Rubber and synthetic plastics, such as *catalin,* are being used for the finished product. To prevent the necessity for repeatedly referring to the two distinct steps, molding and casting, as a unit, the word *moulage* is used to express both. It is of French origin (mouler), meaning to cast or to mold. It should be understood, however, that molding and casting are processes for reproducing an object in form, texture, and often in color, identical in appearance with the original from which the copy or reproduction is made. The mold is the negative; the cast is the positive. The words *pattern* and *model* are used to express the original from which the mold is made. They are used for clarification and amplification, and to prevent repetition and confusion. Since it is possible to make molded and cast prostheses of hands, and casts to cover up scar depressions visible through thin hose on the legs of women, the subject as a whole will be referred to as *moulage prosthesis.* The word *moulage* differentiates the molded and cast prosthesis from the prosthetic appliance which is purely mechanical, such as constructed artificial legs or hands crudely carved from wood and worn with gloves.

Rubber Latex.—The use of rubber latex finally has been established as one of the best materials for the reproduction of artificial parts to be worn on the human body. Synthetic rubber (neoprene) latex is also being employed for this purpose at present. The first mention of rubber latex was made by Clarke[1] and elaborated upon by Bulbulian.[2, 3] In 1936 Mr. Gilbert Blumberg was sent from the Department of Art of the School of Medicine, University of Maryland, to the Mayo Clinic to do moulage work in agar, wax, rubber, and similar

*From the Department of Moulage and Prosthesis, Army Medical Museum.
†Captain, Sanatory Corps, Army of the United States.
Received for publication, April 1, 1943.

materials. Bulbulian evidently used the rubber materials employed there by Blumberg. Further articles by Clarke[4, 5] were written to simplify the technique and to establish a knowledge of the wearing qualities of latex prostheses. Up to this time vulcanite, a hard opaque milled and vulcanized rubber material, was used extensively by dentists for the making of false gums, for holding porcelain teeth, for artificial palates, and similar devices. Kazanjian, Rowe, and Young[6] wrote an interesting article on vulcanite for use in preparing prostheses of the nose and areas around the eyes. Flesh is translucent. This fact can be established by holding the fingers over a burning incandescent electric bulb or flashlight head in a darkened room. Unfortunately, vulcanite is rigid and opaque. It will not move with the face as it assumes various expressions. The prosthesis for the face, if properly made of rubber latex, is soft, flexible, and more fleshlike in appearance. It lends itself more readily to the application of cosmetics and for these reasons is more suitable than vulcanite. Rubber latex can also be made suitably stiff for prosthetic arms, hands, and fingers.

Rubber latex, however, has its own shortcomings and difficulties. Unless properly prepared it darkens on exposure to sunlight. Fugitive or nonpermanent colors used in simulating flesh tones will bleach from the set prosthesis. Shrinkage will occur. Seam lines may appear on the surface of a cast where two or more pieces constitute the mold. All of these disadvantages can be overcome. The methods of doing so will be described. No amount of description or the release of so-called trade secrets, however, will take the place of knowledge gained from the actual working with the necessary materials and from carefully planned and executed workmanship. The information herewith given is substantiated by hundreds of tests and experiments. This approach to the subject is presented because few processes are foolproof. For example, plaster of Paris may be added to water to obtain a homogeneous mixture, but it is more difficult to prepare a smooth mixture if water is added to a quantity of plaster of Paris. Nevertheless, the latter process has been attempted by the novice on numerous occasions. An elementary knowledge of moulage practices is absolutely essential. For this reason *Molding and Casting*[1] is strongly recommended as a reference.

The making of agar molds has been described fully[7] and will not be discussed here. The steps required for producing the prostheses from plaster molds also have been explained.[4] Prostheses or positives of many kinds, however, can be produced from many types of molds, such as those made of rubber, wax, glue, metal, and synthetic plastics.

Because of the demands of World War II the supply of agar has become somewhat limited. Other materials are being substituted for molding and casting with varying degrees of success. An extractive of the seaweed *Chondrus crispus*, commonly known as Irish moss or kelp, is being used in combination with agar in different proportions for the best results. Considerable research should be done on Irish moss to perfect formulas more suitable for moulage purposes.

Another derivative of kelp that is proving more successful than Irish moss is algin or algic acid. It is a protein of marine algae obtained as a by-product

in the preparation of iodine from kelp. Those interested in pursuing this subject should consult American patent No. 2,249,694, "Material for Taking Impressions for Dental and Other Purposes," issued July 15, 1941.

Fig. 1.—A plaster cast is made of the patient.

RUBBER MOLDS AND CASTS

Gum Rubber.—Rubber alone is seldom used for the making of rubber products. It invariably is compounded with other ingredients and these materials greatly influence the properties, quality, and cost of the finished article. It is necessary to mix them with the dried rubber gum by milling, or to the latex or latex paste by agitation. Since this text does not discuss dried rubber, only latex will be considered. The ingredients for mixing with latex are divided into two forms, powders and liquids. Often the powders are converted into liquid or paste mixes for convenience of incorporation; otherwise, the powders may coagulate the latex when stirred into it or the latex will coagulate when stirred into the powder. Of course, this greatly depends on the concentration

of the latex or its dry rubber content, which is spoken of in relation to the *total solid* content of the latex and is an important consideration at all times.

Rubber latex may be procured in two forms,* the unvulcanized latex and the vulcanized latex, often spoken of as prevulcanized latex. The latter form is the simplest to use, but the methods of using both are herewith given.

Fig. 2.—A wax nose is modeled onto the plaster cast or molded and cast from a donor and put in place on the plaster cast.

Unvulcanized Latex.—The unvulcanized or common rubber latex generally requires, in addition to fillers, a vulcanizing ingredient (sulfur), an agent to speed vulcanization (accelerator), a thickening agent (zinc oxide), and a preserving agent (antioxidant). A simple formula for this purpose is:

Rubber, such as latex concentrate	100	parts
Sulfur, flowers of	2	parts

*At present the use of rubber is greatly restricted because of the war. The amount required for prosthetic work is so small and is employed for such an excellent purpose, however, that an application may be made through the Rubber Reserve Board for the small quantities necessary for this work.

Accelerator (Captax)	0.5 parts
Zinc oxide	3 parts
Antioxidant	1 part
Color	q.s.

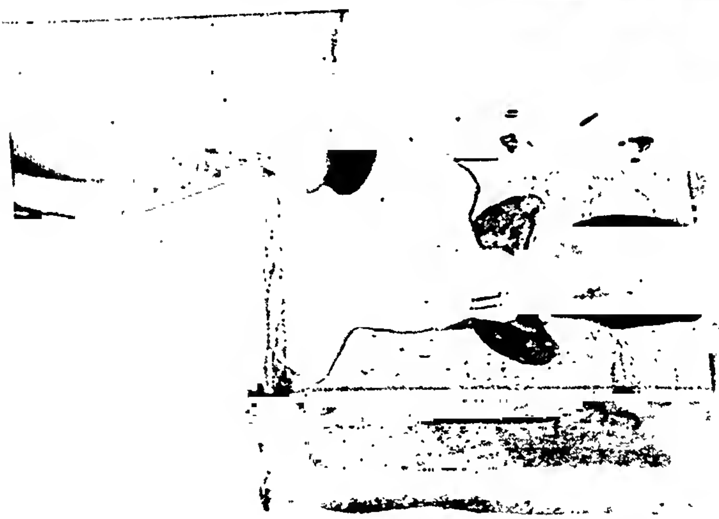

Fig. 3.—A. The wax nose is removed from the plaster cast and painted with a plaster-water mixture on one side only. It is then imbedded into a plaster-water mixture in a box made of glass. Registration notches are cut into the set plaster and a separating medium is applied. A piece of plasteline is put in place to form a pouring funnel in the second half of the plaster mold.
B. The second half of the mold is made.

To this mixture can be added fillers, such as clays, cellucotton, and other ingredients, to increase its bulk and to make it pastelike so that it will remain on a vertical surface to suit specific purposes. A clay filler usually serves best in making a cast; cellucotton or wood flour is more suitable for making molds. Clays are satisfactory for incorporating in latex mixes where the cast is to be poured into plaster molds. White clays and zinc oxide counteract the darkening of set latex when exposed to sunlight.

Unvulcanized or common latex must be vulcanized by heat in one form or another to preserve the rubber. It is done after the rubber has set within the mold and generally before the cast is removed. A rubber mold can be vulcanized on the pattern unless the pattern is made of wax. Unvulcanized latex has a tendency to stick to the pattern or mold unless thoroughly dry and vulcanized; therefore, unvulcanized rubber casts are vulcanized while still in the mold.

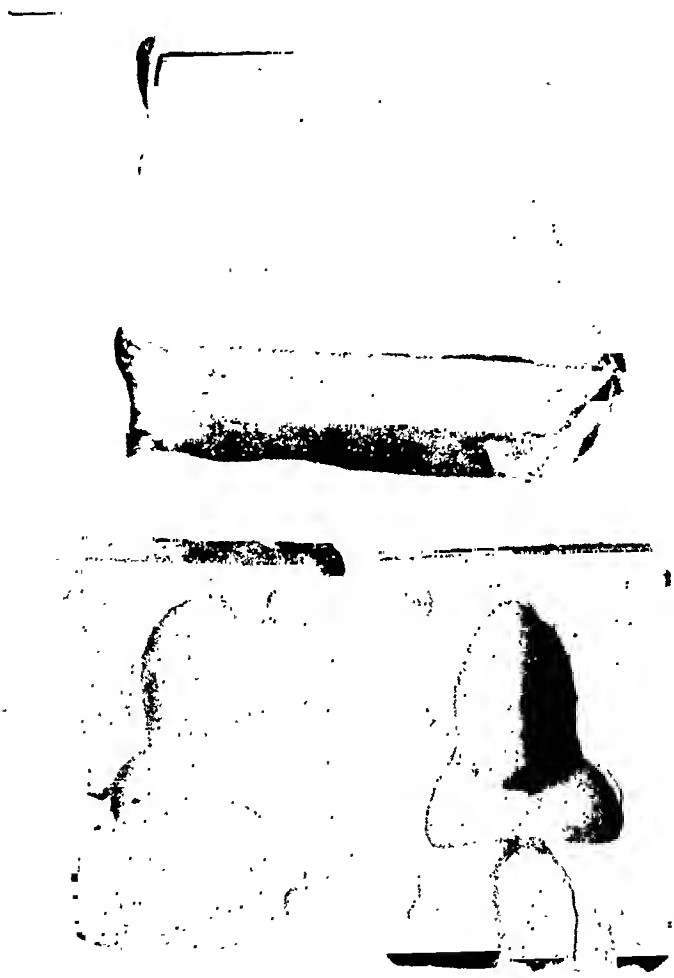

Fig. 4.—*A*. The filled glass box constituting the completed two-piece mold.
B. The mold is opened and the wax cast is removed. If there are undercuts in the cast it may be necessary to destroy the cast to open the mold. In such a case boiling water is poured over the closed mold. The mold will open but the wax cast will be melted.

Vulcanized Latex.—The moulage worker and prosthetist can save considerable time and effort by using vulcanized latex. This is identical in appearance with unvulcanized or common latex; however, it acts in an entirely different manner toward the mold. It will not stick or adhere to plaster and similar patterns or molds when it has set or coagulated. Nevertheless, it should not be removed from the pattern or mold until comparatively dry; otherwise the cast will not retain its shape.

Fillers.—Cellucotton, wood flour, clays, and similar fillers may be added to vulcanized latex in making rubber molds. Since the latex is vulcanized as a liquid before shipment, additional vulcanization is unnecessary. Clays may be added to the prosthetic cast to prevent darkening in sunlight. It should be remembered, however, that the more clay that is added the more translucency is lost. For prosthetic work Bulbulian recommends the addition of 3 Gm. of zinc oxide in a water dispersion to 200 c.c. of vulcanized latex (Vultex H 235). According to tests this will not prevent darkening of the latex. Furthermore, this additional zinc oxide may produce cracking of the resulting prosthesis, since Vultex H 235 already contains some zinc oxide. The cracking, however, may not occur for some months. A white clay filler would be more suitable in this case. The clays do not have the opacity or covering power of zinc oxide; therefore, more than 3 Gm. of clay to 200 c.c. of rubber may be used. This is 1½ per cent. White China clay and Dixie clay suggest themselves for this purpose. Dixie clay, when used in great quantities, not only produces opacity but causes a stiffening of the resulting prosthesis. Titanium dioxide is considered the whitest of the common fillers and possesses a high degree of fastness to light and vulcanization. It is a bright white powder free of yellow tinge; it does not affect the aging of the rubber, but is rather opaque and has considerable covering power. Therefore it must be used in small quantities and should be ground thoroughly in water before use.

The General Latex and Chemical Company* manufactures an excellent clay filler already dispersed in water that is most suitable for prosthetic work. It is their No. H 222, Part B, and can be used in conjunction with Vultex F 293 or H 235. It may be compounded in the Vultex up to 10 per cent without obtaining great opacity or loss of translucency. Of course, this depends on the color and opacity to be produced.

An excess of fillers and sulfur causes rubber to become stiff on drying. A formula for prosthetic work should not include enough of these ingredients to be objectionable. In some cases, however, extreme lightness is desirable. The stiffening of the prosthesis can be offset by pouring a thin rubber coating into the mold, and by then forcing sponge rubber or foamed latex between the thin layers. This produces a lifelike prosthesis that lends itself to trimming of seam lines and yet remains sufficiently flexible to move on the flesh as different expressions are assumed. Sponge rubber alone does not lend itself to trimming and is not as natural in appearance. It does allow the penetration of air through its pores and this has some advantages. Sponge or foamed rubber will be discussed more fully later in this text.

A simple formula containing vulcanized latex is as follows:

Vultex F 293	10 parts by volume
Filler H 222, Part B	1 part by volume
Pontamine fast red 8 B1 (in water)	q.s.

Rubber latex turns slightly yellow on setting and drying. Caucasian skin color generally is obtained by mixing reds and yellows. Since the latex itself is light yellow on drying, only the red is added. Other reds than the Pontamine

*Cambridge, Mass.

fast red mentioned can be used. Colors and coloring of the finished prosthesis will be discussed in detail in a future article. It should be mentioned, however, that the latex stock solution is given a light basic color in the latex mix to resemble a flesh color. This is done with water-soluble dyes having an alkaline reaction and containing no copper. The final coloring is done with oil and alcohol-soluble dyes, not with pigments as is the common belief. Oil-soluble dyes penetrate the dry rubber and blend in a soft homogeneous manner. The dye-colored prosthesis can be washed and scrubbed with a stiff brush immediately after coloring without any loss of color. If pigments were used they would be scrubbed off because they only lie on the surface. Alcohol-soluble dyes do not penetrate the rubber nor do they blend or bleed out into the rubber. When the prosthesis is colored properly, the necessity for the final use of cosmetics becomes lessened or eliminated.

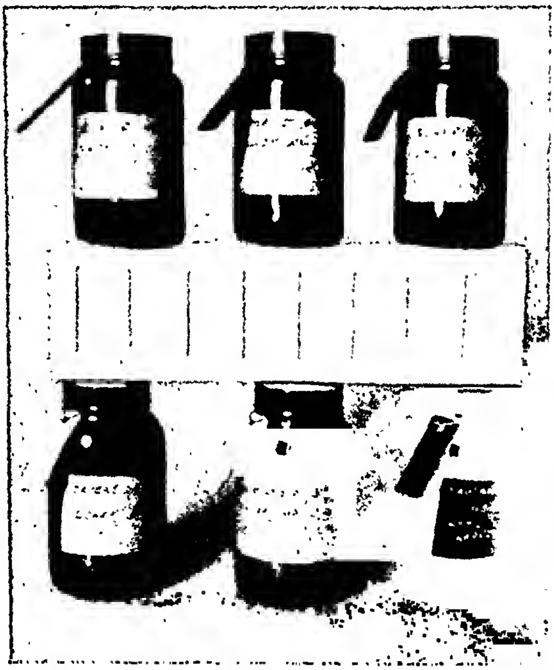

Fig. 5.—Rubber stock solutions of both Caucasian and Negroid skin colors. The plaster block between the bottles is used to obtain dried samples of the various colors. The depressions in this block are numbered from one to eight for specifying the intensity of color.

Pliability.—As already mentioned, the finished prosthesis should possess enough pliability when used as an artificial part on the face to move with the remaining features as they assume various expressions. A thick, solid prosthesis would not have sufficient pliability to move with the features without separating from the skin at corners where the prosthesis joins the face. An example of this inflexibility would be noted in the outer borders of the upper lip. Three alternative remedies for this defect may be considered. The prosthesis can be made rather thin and thus lend itself more readily to shrinkage and distortions, or a thin shell may be filled with sponge rubber to give body to the resulting prosthesis. In the latter instance pliability still remains, in spite of the fact that

the prosthesis seems thick. The third alternative is the use of a softening medium in the latex mix, such as castor oil, mineral oil, and stearic acid. These oils must be converted into emulsions or suspensions in aqueous mediums before being incorporated into the latex mix. Soft soap may be used for this purpose as could any of the substances of a colloidal nature which serve as stabilizers of rubber latex itself, such as casein. Complete information on this subject will be found in most books on rubber latex.

Sponge Rubber.—Prostheses have been made of sponge rubber alone and are rather light and pliable. Air will pass through them, and for this reason it is assumed that they would be more comfortable to wear, since they give the tissues a chance to breathe beneath the artificial organ. In the author's opinion the prosthesis made of sponge rubber is impractical in most cases. It does not lend itself to the trimming of seam lines after removal from the mold. It becomes distorted and remains so. If cosmetics and adhesives are applied to the surface the air cannot pass through the pores. Sponge rubber does not have a natural appearance. Sometimes a comparatively stiff rubber prosthesis is desired, such as a hand, for example. As a matter of fact, a microcrystalline wax is poured into the prostheses of hands to increase the stiffness susufficiently to allow the wearer to hold a pen or pencil for writing or tableware for eating. If the rubber fingers are filled with this plastic wax, they can be moved to adequate positions for holding such implements. The wax core, which in itself is pliable but remains where placed without cracking, is thick enough for this purpose. Microcrystalline waxes will be discussed in detail in another article.

When pliability and lightness are desired in prostheses for parts of the face, both solid and sponge rubbers are used. The technique for producing such a prosthesis is simple: The formula having the correct basic flesh color (monochrome) and other compounding ingredients is poured into the plaster mold and allowed to remain until a deposit or coating of sufficient thickness is formed. This depends on the dryness of the mold, the size of the resulting prosthesis, and the time the mixture remains in the mold. The longer it stays in the mold the thicker the deposit. In small prostheses a coat of sufficient thickness will be built up in a dry mold within three or four minutes or less. The rubber is then poured from the mold and the mold allowed to drain. This can be done by placing the mold on the spout of the bottle from which the rubber was poured. As the mold drains, a small amount of the same formula is put in a dish and agitated by an egg beater until it is well foamed. The rubber should gain at least three times its volume after beating. It will be sluggish and will not pour as readily into the mold. A small amount may be poured into the opening of the mold, however. A large rubber bulb is then used to force this sponge rubber into the mold and the process is repeated until the mold cannot hold more rubber. The mold is then placed in a warm place until the cast or prosthesis is thoroughly dry. This should take place in from twelve to twenty-four hours when the mold is placed in a drying cabinet or on a heated radiator. If the cast is removed too soon it will shrink and become distorted.

Prostheses that are to be enlarged by soaking in benzine[8] for further casting to offset shrinkage should not be cast in sponge rubber, because they disintegrate more quickly in the expanding agent than solid rubber does.

Preparing Sponge Rubber.—Sponge or foamed rubber can be prepared from ordinary latex containing the compounding and vulcanizing ingredients, or from vulcanized latex. An emulsifying agent such as liquid soap is added to

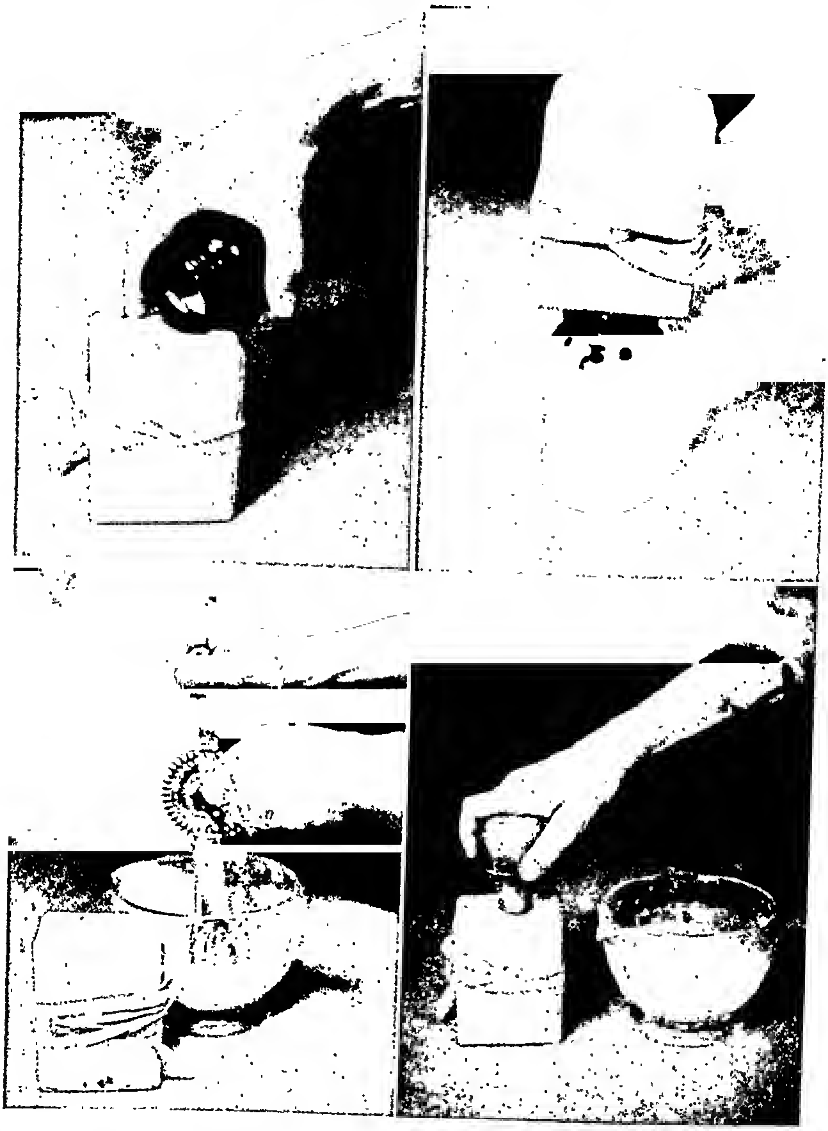

Fig. 6.—*A*. In making a prosthetic rubber nose the cast is poured from the desired stock solution.

B. If it is desirable to use a sponge rubber center for the prosthesis, the rubber is poured from the mold back into the bottle after being in the mold for a minute or more.

C. Part of the rubber from the same stock solution is foamed with an egg beater to form the sponge rubber.

D. Some of this sponge rubber is poured into the mold and forced down with a rubber bulb. From time to time the process must be repeated.

the latex formula in order to stabilize the foam; a setting agent, which is a coagulant having a delayed action, is also added to set the foam. The ingredients are adjusted in the formula, and treatment of the mold is carried out in a manner so that the foam produced by beating, whipping, or blowing the latex mixture is stabilized in this condition. Sodium bicarbonate also may be employed for foaming rubber by effervescence, but this method is not as dependable as

the introduction of air into the latex mix by mechanical means. The soap and salt are added to the mix so that the bubbles will not burst or subside until the setting agent coagulates the whole. The same metallic salts may be used in sponge rubber as in the mixes for coagulating coats or deposits on nonporous molds, such as those of agar, metal, or rubber. After the bubbles and film have set, the rubber is dried. By adjusting the proportion of the setting agent and the temperature of the mold, the time in which the latex froth will set can be controlled readily. Some of the common salts used in sponging latex are calcium sulfate, magnesium sulfate, and calcium chloride. The proportion used is necessarily small, approximately 1/40 part to the latex mix. The salts should be dissolved in water before being added to the latex mix.

SOFTENERS AND PLASTICIZERS

Sometimes it is desirable to have a prosthesis that is solid as well as soft, but made without sponge or foamed rubber. For this purpose softeners or plasticizers are incorporated into the latex mix before it is poured into the mold. These softening agents render the rubber impression more pliable, a desirable feature in facial prostheses which must move with the muscles.

The following are two formulas suitable for this purpose:

No. 1

STEARIC ACID OR PARAFFIN FORMULA

Stearic acid or paraffin	4 Parts
Oleic acid	1 Part
Water	5 Parts
Caustic potash	3 Per cent of weight of stearic acid or paraffin
Ammonia solution	3 Per cent of 26° Be

The stearic acid or paraffin is melted with the oleic acid while stirring vigorously. These ingredients are stirred into the water containing the caustic potash. The ammonia is added while the stirring is continued. The emulsion is carried out best at 70° to 80° C.

No. 2

MINERAL OR PARAFFIN OIL FORMULA

A mineral or paraffin oil emulsion may be prepared by adding 2 to 5 per cent of oleic acid to the oil, and then by rapidly stirring the mixture into water containing 1 per cent of 26 Be ammonia solution. This emulsion may be prepared cold with a concentration of 50 to 60 per cent of oil.

Up to 10 per cent of the paraffin or stearic acid emulsion may be used in the latex mix; but if 2 per cent is exceeded, blooming usually occurs. The mineral oil emulsion does not bloom as readily as the paraffin formula and as much as 10 per cent may be used; however, a staining is more likely to occur with this formula than with paraffin.

For prosthetic work it is advisable to mix stock solutions of one or both of these plasticizers to be incorporated at the time a latex mix is prepared for a specific prosthesis.

Coagulum Deposit.—As previously mentioned, it may be necessary in producing the cast to build up a coagulum deposit on nonporous agar and similar molds to develop sufficient thickness for the cast to be of practical value. The

Fig. 7.—*A*. When the cast is completely dry, the mold is opened and the rubber prosthesis is removed. This illustration shows the front view of the untrimmed prosthesis immediately after removal from the mold.

B. The back view of the same prosthesis showing the area to be joined to the skin.

C. [illegible] a Negro immediately after removal from the mold.

coagulating agent can be incorporated into the agar-molding composition, or it may be applied to the surface of the mold. A coagulating agent for mixing with agar compositions is magnesium sulfate (epsom salts), because it has no detrimental effect on the agar. Plaster of Paris or unglazed terra cotta molds need no coagulating agents, since these porous molds absorb the water from the latex

mix and thereby build up a coagulum deposit next to the mold surfaces. Metal molds can be used for rubber casting, since a coagulum deposit can be built up on a metal mold by the application of heat to the mold before the deposit is made. A rubber mold can be used to cast rubber, because a coagulum deposit can be built up on a rubber mold which has been treated previously with a coagulant and a separating medium. A wax mold can be treated with a coagulating agent only, as a separating medium is unnecessary.

A. B.

C. D.

Fig. 8.—The making of a prosthetic rubber hand and arm. *A.* The agar composition is poured into a cloth bag. After it has cooled to near its setting point, the hand and arm are inserted into the bag. The bag is placed in ice water where it remains until the agar has completely set. *B.* Before removing the hand, a slit is made opposite the wrist in the agar mold and cloth bag. The hand is then removed. *C.* The rubber latex composition is poured into the bag where it is allowed to stand until a coagulum deposit of about one eighth of an inch is built up next to the mold. The excess rubber is then poured out. *D.* After the coagulum deposit has fully set, but not dried, a melted microcrystalline flexible wax is poured as a core into the rubber cast while the cast is still in the mold.

Where a thick deposit is necessary it is advisable to use a concentrated latex. The thickness of the deposit is dependent on a number of factors, some of which can be controlled at the compounding stage. If unvulcanized latex is used, the simple addition of the vulcanizing ingredients increases the viscosity of the latex. The addition of 2 or 3 per cent of zinc oxide in particular has been found to have an appreciable thickening effect on latex. If more than 5 per cent is added,

a complete coagulation of the entire mixture may result. Some soluble metallic salts, such as calcium sulfate in small quantities (0.3 per cent of the dry rubber content), cause a slight thickening and render the latex sensitive to local heating. By this addition or pretreating of the latex mix, a firm thick coagulum may be built up when the mixture comes in contact with hot surfaces. Salts of magnesium and zinc also serve for this purpose.

Where a thick coagulum deposit is necessary on nonporous molds, the mold may be dipped, sprayed, or painted with dilute acetic acid. Often this is done after the first thin layer of latex has been deposited. The second layer will then be rather thick. After the deposit has completely coagulated, the excess acid should be washed away with water.

The coagulants commonly employed are acetic acid, formic acid, calcium chloride, acetate, nitrate or formate, zinc chloride, and ammonium acetate in water. Acetone or alcohol solutions are also used, depending upon the molding material and the conditions under which it is desired to effect a coagulation. Methyl alcohol has been of value, because of its readily wetting properties. Two or more coagulants have been used together, as, for example, calcium chloride (2½ per cent) in equal parts of methyl alcohol and water. In fact, I have found calcium chloride and acetic acid among the best coagulants for prosthetic work, according to the problem to be solved. The salt was used in the mix and the acid was applied to the surface of molds. The coagulating agent may be painted or sprayed on the surface of the mold, or it may be poured into closed molds and drained out. It may or may not be dried on the form. A coagulant should be chosen and applied in such a manner, however, that the rubber will be coagulated immediately, so that there will be little tendency for the latex to flow or cause "sags." "Sags" may be the result of two thin coagulated surfaces of latex between which is a deposit of uncoagulated latex. They may also be produced by coagulating one layer over another in the same mold, a practice which is not always good. It is best to try to build up a deposit of sufficient thickness in one pouring. After the deposit is made it must be dried. In the case of prosthetic rubber hands, a melted microcrystalline wax is poured into the hollow hand before it is removed from the mold to prevent shrinkage of the rubber and to make the hand of practical use. In such a case an unvulcanized latex formula may be used, as the hot wax will vulcanize the thin rubber deposit.

STEPS IN MAKING A PROSTHETIC HAND

A practical example of building up a coagulum deposit is obvious when a rubber pattern is to be made from an agar mold for a prosthetic hand and arm. Briefly, the procedure is as follows. A one-piece agar mold is made of the donor's hand and arm by filling a cloth bag with melted agar composition containing epsom salts. The composition should be cooled to a point where it is comfortable to the donor. His hand and arm are inserted into the bag and the bag is placed in a deep bucket of ice water until the agar sets. If started at the right temperature this should take from one-half to three-quarters of an hour. When the agar has set completely the hand is withdrawn. Before withdrawing the hand, however, a slit should be cut on one side of the bag of agar composition opposite the wrist to allow the mold to spread, so that the largest part of and

can pass through the small opening formerly occupied by the wrist. After the hand is removed a gauze bandage is tied around the agar mold at the wrist to close the expansion slit. A coagulating agent is poured into the bag to further treat the surface of the mold. This is drained out and hot air forced in to dry the surface. The mold is then filled with rubber latex which is allowed to stand until a deposit of one-eighth inch is built up on the sides of the agar mold. This deposit is caused by the epsom salts in the agar, plus the surface coagulant. After a one-eighth inch deposit is built up the remaining rubber is poured out

Fig. 9.—The making of a prosthetic rubber hand. *A*. The agar mold is placed in ice water. *B*. The mold is cut opposite the wrist. *C*. The rubber is poured into the mold. After setting, the wax is poured into the cast to form the core. *D*. The cloth bag is removed, and then the agar mold is cut into blocks and broken away from the cast. The rubber hand is still wet and must dry on the wax core. The seam line caused by cutting the agar mold to release the hand is plainly visible on the wrist of the rubber cast. This is trimmed off with hot instruments after the cast has fully dried.

and the mold is placed on its open end over a collecting pan to permit it to drain. When the rubber stops dripping, a hair drier, which is a fan blowing heated air through a small opening, is placed in the open end of the cast to aid in further coagulation of the cast while it is still in the mold. After the rubber cast has coagulated sufficiently to stand handling of the edges, it is filled with a microcrystalline wax to serve as a core to prevent shrinkage of the cast when the agar mold is removed. The rubber at this stage should not be com-

pletely dry, or cracking will result. If the wax is not poured at this time the cast will continue to dry from the inside and considerable shrinkage will take place. The agar mold is removed after the wax has set completely but before the rubber is dry. On removal, it will be found that seam lines were formed on the rubber where the mold was cut opposite the wrist. These are dressed off with heated instruments and all other defects are repaired. Although such a hand can be used as a prosthesis for the patient, it is far better to use it as a pattern for making a one-piece plaster mold so that many duplicates can be made. This is done by applying plaster to the rubber hand to form the mold. After the mold is made, it is placed in an oven and heated until the wax core of the cast is melted. The wax is then poured out. A thin rubber shell of a hand incased in a plaster mold remains. By grasping the rubber edges the collapsible hand may be pulled from the mold. Duplicate hands are then made in the same mold by pouring rubber into it, allowing the deposit to be built up, and pouring out the excess latex. The rubber cast may be dried from within by using the hair drier. The duplicate hand is removed and the process repeated until a sufficient number of prostheses are obtained. The flexible microcrystalline wax is poured into the rubber hands after removal from the plaster mold to give them stiffness and to make them practical for grasping objects. The fingers of the prosthesis are simply bent with the natural hand into the correct position for practical use. The object to be used is then placed into the prosthetic hand with the natural hand.

The prosthetic hand is colored with oil-soluble dyes for softly blended effects and with alcohol-soluble dyes for detail. The oil-soluble dyes bleed into the rubber and permeate the color through the entire thickness of rubber. Alcohol-soluble dyes do not bleed into the rubber but remain where they are placed; therefore, they can easily be washed from the surface. This can be prevented by the application of a fine coat of semimatte lacquer or by the application of a latent rubber solvent to the prosthesis. Such a solvent opens the pores of the rubber temporarily to absorb the dye. The solvent evaporates quickly without causing the surface of the prosthesis to lose detail. Mixtures of turpentine and benzine serve well for this purpose. The turpentine acts slowly on the rubber, whereas the benzine acts rather quickly; therefore, the turpentine is used as a retarding agent for the benzine. Immediately after these materials are applied, the prosthesis can be washed with soap and water to see if the desired effect thus obtained will be permanent.

CLINICAL AND EXPERIMENTAL

BLOOD PRESSURE FLUCTUATIONS IN BRONCHIAL ASTHMA*

II. Effect of Epinephrine and Aminophyllin

Howard Osgood, M.D., and Francis E. Ehret, M.D., Buffalo, N. Y.

THE occurrence in bronchial asthma of excessive fluctuations of the systemic systolic blood pressure, synchronous with the respiratory cycle, has been noted in the past by a number of observers, among whom are Tinel and Jacquelin,[1] Rackemann,[2] and Feinberg.[3]

In a recent article[4] one of us drew attention to these fluctuations, and reported observations on a number of asthmatic patients under various circumstances. The conclusions, which agreed closely with those of Tinel and Jacquelin, were: (1) During the asthmatic paroxysm there is constantly present an increase above normal in the respiratory fluctuation of the systolic blood pressure. (2) The amplitude of this fluctuation parallels closely the severity of the asthmatic dyspnea. (3) When the asthmatic paroxysm has ended, the respiratory systolic fluctuation returns to normal limits. An exception to the third statement has been noted: In certain chronic asthmatic patients, in whom irreversible changes have taken place in the lungs, there may be present at times a moderate increase in the respiratory systolic fluctuation, even though the patient appears to be in little or no distress.

Further observations disclosed that the systolic blood pressure uniformly reaches the highest point during expiration and falls to its lowest point during inspiration, both during the paroxysm and during the asthma-free state. Certain experiments with respiratory obstruction in anesthetized cats and in healthy young men, which Osgood has reported,[5] showed a similar increase in the respiratory systolic fluctuation with increasing obstruction. The timing of the high

*From the Medical Services and Allergy Clinic of The Buffalo General Hospital.
Received for publication, December 23, 1942.

and low points of the fluctuation in the respiratory cycle was also the same in these experiments as in bronchial asthma.

The detection and measurement of this respiratory systolic fluctuation are readily made, using an ordinary sphygmomanometer. The method was described in a previous paper.[4] The normal fluctuation in healthy persons with quiet breathing averages about 4 mm. Hg with a range from 2 mm. to 8 mm.

The present paper concerns the effect on this fluctuation of epinephrine and of aminophyllin, administered for the relief of bronchial asthma.

Relief from the dyspnea of bronchial asthma induced by the subcutaneous injection of epinephrine is usually prompt in appearance. It is evidenced subjectively by a rapid diminution of the respiratory distress, and objectively by a decrease or disappearance of the asthmatic wheezes and râles from the lungs: or, if there is much mucus present, by a coarsening of the asthmatic sounds in the chest, and sometimes by the expectoration of secretion. There is also a lessening or a complete cessation of the vigorous muscular efforts of respiration and of the retraction of the suprasternal and supraclavicular tissues.

Following the intravenous administration of aminophyllin with relief, the changes are somewhat different. They are not so marked and are often slower in appearing. They consist subjectively of a feeling of general relaxation and of release from dyspnea, which may be prompt or delayed one-half to one hour, and sometimes of a fleeting feeling of warmth. There may also be a cough with evacuation of sputum. Objectively there is a decrease in the respiratory efforts, as with epinephrine. The retraction of the soft tissues of the chest and the asthmatic sounds in the lungs, however, are apt to diminish to a lesser degree than the subjective relief would seem to indicate. After both drugs it is not difficult to estimate clinically the degree of relief afforded, utilizing these various phenomena.

BLOOD PRESSURE FINDINGS AFTER EPINEPHRINE

Charts I and II present the blood pressure findings in seven patients, all suffering from moderate or severe bronchial asthma at the time. As on all subsequent charts, the high and low points reached by the systolic blood pressure during expiration and inspiration, respectively, are shown in mm. Hg, and the respiratory fluctuation is indicated by the cross-hatching between these points. The degree of dyspnea at the moment of each reading is indicated by the solid black column at the bottom. Below the column is marked the time of the injection of medication and of each reading.

It will be noted that the systolic blood pressure showed wide fluctuations before the epinephrine was given. Within ten to twenty minutes after the injection the systolic fluctuation had returned to within normal limits in those patients who obtained clinical relief.

Patient F. N. (Chart I), suffering from chronic asthma of the "mixed" type, secured prompt relief, and in twenty minutes following the injection of epinephrine the systolic fluctuation had dropped from 14 mm. to 3 mm. On the other hand, M. P. (Chart II), whose chronic asthma was also of the mixed type, obtained practically no relief, and the respiratory systolic fluctuation, which had been 28 mm. beforehand, was still 23 mm. thirty-three minutes after the injection.

The patient C. B. (Chart II) suffered from chronic asthma of the intrinsic type associated with hyperplastic sinusitis. His severe, recurrent attacks were usually relieved temporarily by epinephrine. A reading in May, 1940, during a severe paroxysm, showed a systolic fluctuation with respiration of 24 mm. On August 3, 1940, he was seen in great distress, with his skin gray and sweating. The respiratory systolic fluctuation was 50 mm., one of the greatest we have observed. He was given ½ c.c. of 1 to 1000 epinephrine and 1 c.c. of epinephrine in oil, 1 to 500. He experienced marked relief, and twenty minutes after the injection the systolic fluctuation had dropped to 6 mm. A reading eight months later, when he was in no apparent distress, gave a systolic fluctuation of 12 mm. His lungs, however, showed numerous coarse wheezes throughout.

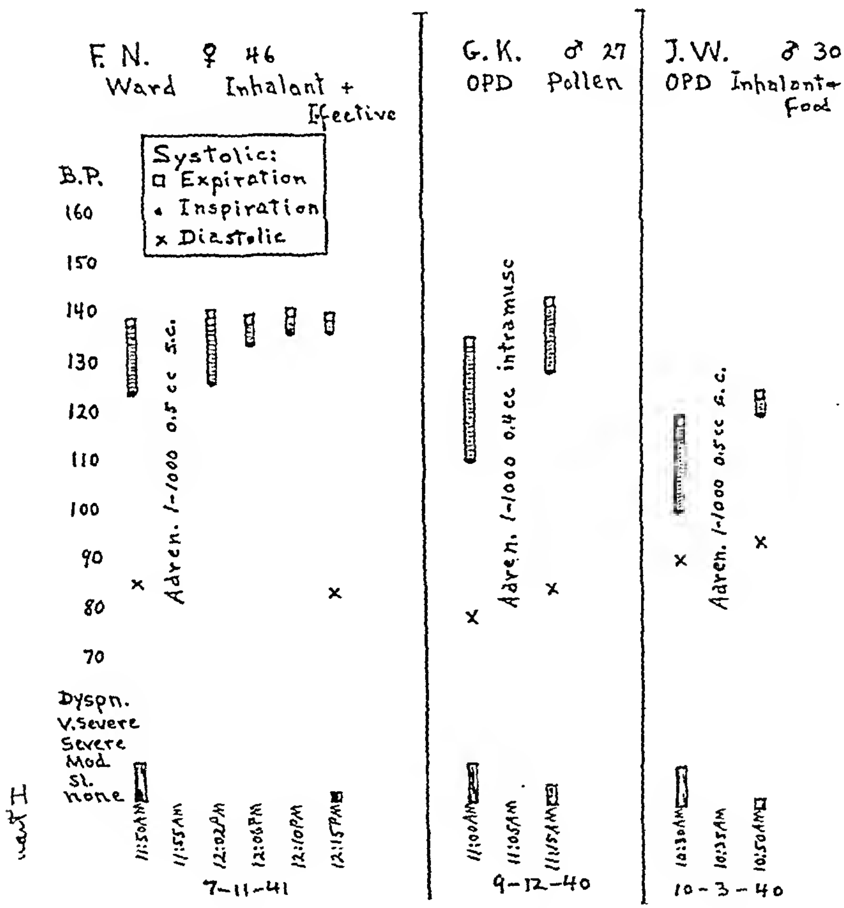

Chart I.—The effect on the respiratory systolic fluctuation of epinephrine administered for the relief of bronchial asthma.

BLOOD PRESSURE FINDINGS AFTER AMINOPHYLLIN

The response of the respiratory systolic fluctuation to the intravenous injection of aminophyllin differs from that of epinephrine. On Charts III and IV are recorded observations on two patients to whom epinephrine and aminophyllin were given at different times for relief of their asthma.

Patient A. B. (Chart III) was sensitive to tree, grass, and weed pollens, and to some other unidentified factors, probably intrinsic. Her paroxysms were periodic and severe, and epinephrine usually gave relief. On April 17th she was seen in a severe attack; her lungs showed many wheezes. The respiratory fluctuation of her systolic pressure was 24 mm. seated, and 38 mm. recumbent. Six-tenths c.c. of 1 to 1000 epinephrine was given subcutaneously, while recumbent. Sixteen minutes later she had no distress and the respiratory systolic fluctuation was 6 mm. recumbent. A week later she was again seen in a moderately severe paroxysm with wheezes throughout her lungs. The respiratory systolic fluctuation was 26 mm. Aminophyllin, 0.24 Gm. in 10 c.c., was given intravenously. Twenty-five minutes later she had experienced considerable subjective relief, although not complete, and her lungs still showed many wheezes. The respiratory systolic fluctuation was still 24 mm.; the expiratory peak of her systolic pressure had fallen from 120 mm. to 110 mm.

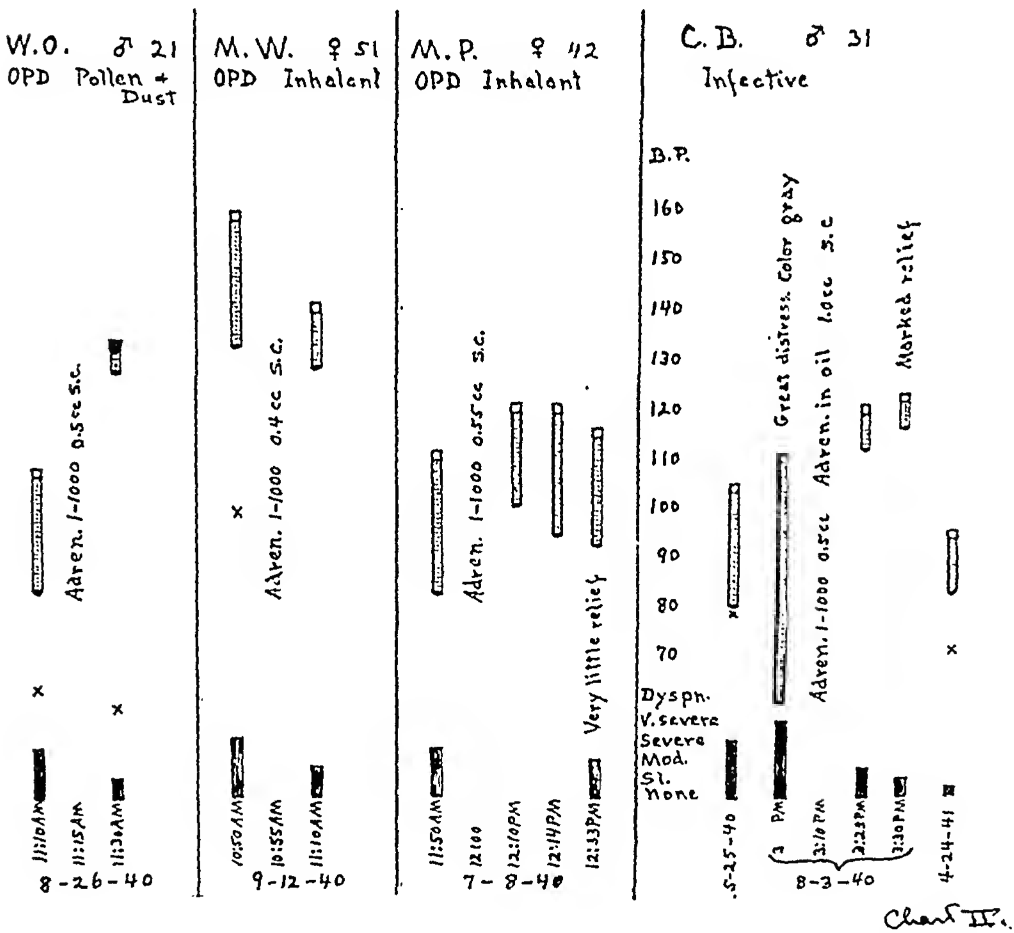

Chart II.—The effect of epinephrine on the respiratory systolic fluctuation in bronchial asthma.

Patient G. H. (Chart IV) was exceedingly sensitive to grass and weed pollens and possibly to molds; her asthma was seasonal. She was seen on July 7 when suffering from severe asthma. The respiratory systolic fluctuation was 18

mm. Epinephrine, 0.8 c.c. in 1 to 1000 solution, was given subcutaneously. Subjective relief was felt in eight minutes, and was marked, though incomplete, in twelve minutes, at which time the respiratory systolic fluctuation was 8 mm. On September 6 she was again having severe asthma. One-half c.c. of 1 to 1000 epinephrine had been injected by her son at 6 A.M. At 7:30 A.M. she was suffering severely, with "tight" wheezes throughout the lungs. The expiratory peak of her systolic pressure was 180 mm. and the respiratory fluctuation was 15 mm. One-half gram of aminophyllin in 20 c.c. was given intravenously. Ten minutes later the expiratory peak of her systolic pressure had fallen to 96 mm.; fifteen minutes after the injection it was 110 mm. She had great subjective relief and began raising considerable sputum. The respiratory systolic fluctuation, however, was still wide: 16 mm. and 20 mm. on two close readings. Twenty-three minutes after the injection, relief was maintained, but the respiratory swing was still 20 mm. Two and a quarter hours later she was somewhat dyspneic with continued expectoration; the respiratory fluctuation was 14 mm. She required no further medication through the day, but was given 1 c.c. of epinephrine in oil at 7:30 P.M. At 10 P.M. she had slight dyspnea and her expiratory systolic peak was 120 mm. with a respiratory fluctuation of 8 mm. The following morning she was asthma-free. The respiratory systolic fluctuation was 8 mm.

Chart V presents the findings in C. G., a married woman aged 29 years, sensitive to pollens and to a number of other inhalants. On October 19 she had been given adrenalin in oil, 1 to 500, at 4 A.M. and at 11 A.M. At 12:30 P.M. she was markedly dyspneic and orthopneic, with retraction of the soft tissues of the chest and sonorous sounds throughout the lungs. The respiratory systolic fluctuation was 40 mm., with the expiratory peak at 140 mm. She was given 0.25 Gm. aminophyllin in 10 c.c. intravenously. Fifteen minutes later she had felt some relief, but the systolic fluctuation was still 40 mm. Relief was progressive, and two hours and forty-five minutes after aminophyllin she was very comfortable, with only slight dyspnea and some wheezes in her lungs. The respiratory fluctuation of her blood pressure, however, was still 26 mm. Two days later she was free of dyspnea and the respiratory fluctuation was 11 mm. and 14 mm. The lungs still contained some sonorous râles.

J. G. (Chart VI), a colored man of 42 years, had long bouts of severe asthma due to intrinsic factors and to foods. He showed at times frequent premature ventricular systoles, although there were no significant electrocardiographic changes or other signs of cardiac disease. His blood Wassermann was negative. Epinephrine afforded so little relief that he refused its administration and asked for aminophyllin. Before injection of the latter drug he would be sitting up, feet over the bedside, wheezing, coughing, and sweating. After its injection he would quiet down in a few minutes and lie semirecumbent, although rarely did his chest clear of wheezes. As will be noted in the chart, the response of the systolic fluctuation to the drug was rather irregular. In general there was a fall in the level of the expiratory peak and a decrease in the respiratory fluctuation, although not so marked as after epinephrine in other patients.

Chart VII gives the blood pressure readings on patient M. M. taken before and after six intravenous injections of aminophyllin and two subcutaneous injections of epinephrine.

She was an unmarried woman, aged 24 years, sensitive to grass and weed pollens, to orris, and to some other inhalants. She had had recurrent attacks of asthma since childhood, which in recent years occurred chiefly in the summer and fall, and lasted several weeks at a time. She had developed surprisingly few permanent changes in the lungs or chest cage. Three years of hyposensitizing treatment had not produced very satisfactory results. Her paroxysms were difficult to control and she was rather "sensitive" to epinephrine. Best relief was secured with aminophyllin, although it was rarely complete and was slow in appearing.

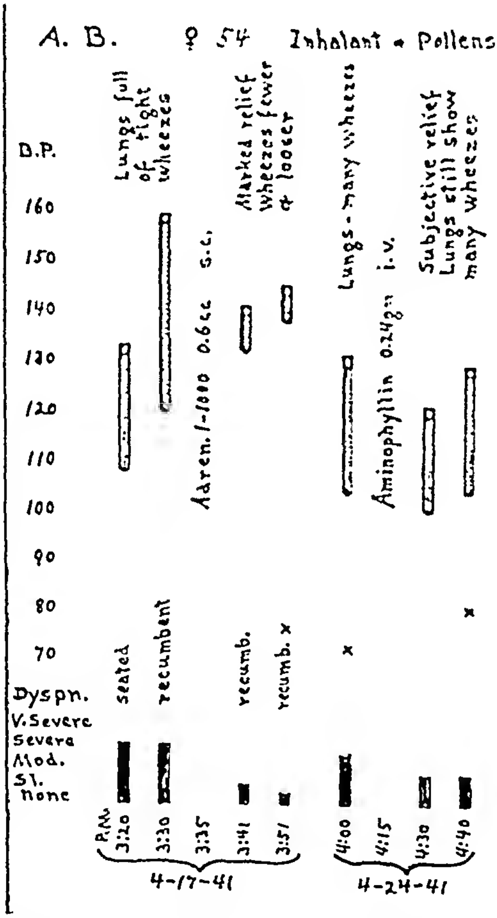

Chart III.—Comparative effects on the respiratory systolic fluctuation of epinephrine and of aminophyllin, administered to a patient in separate paroxysms of asthma.

In her chart it will be noted that with severe dyspnea, the respiratory fluctuation of her systolic blood pressure was wide, varying between 22 mm. and 40 mm. before either drug had been given. After the two epinephrine injections (July 3, 1939, and June 13, 1940) she obtained little or no relief, and the respiratory systolic fluctuation did not decrease in amplitude; the expiratory peak rose slightly.

The six injections of aminophyllin afforded considerable though incomplete relief. She felt "more relaxed" afterwards. Following three of the injections,
